bacteriologically, the colon bacillus would be found in the vast majority of the cases. The common rule was for the disease to run from one week to ten days, when the temperature and pain would subside with more pus in the urine, and then the patient apparently would recover. This recovery might be permanent or only temporary, recurrences occurring before delivery. As a rule the recovery was permanent. Again it might recur after delivery, or in subsequent pregnancies. With regard to the diagnosis, one of the conditions most often confusing was appendicitis. If one relied upon the symptoms when first seen, the picture would be that of appendicitis; but if the urine was examined a differentiation could be readily made. A positive Widal reaction would differentiate pyelitis of pregnancy from typhoid fever. In differentiating pyelitis from cystitis one would not get such tenesmus, the urine would be acid and not alkaline, and one could introduce 150 c.c. of boric acid solution into the bladder without much discomfort; this would be sufficient to rule out cystitis. Of course there might be a cystitis secondary to pyelitis. The pyelitis did seem to be a descending infection through the blood and pelvis of the kidney. With regard to the involvement of the left kidney, this occurred primarily only in one case out of the twenty-five under his observation; in two or three cases the left kidney was involved secondarily. In a recent report of sixty-two cases, in only six was there a primary involvement of the left kidney. The most satisfactory treatment consisted in flushing out the urinary tract with large draughts of water, administering urinary antiseptics, moving the bowels, an ice-bag over the kidney, and giving small doses of opiates for the pain. Some benefit was to be derived from turning the patient on the side opposite the affected one. The prognosis, as all would admit, was an uncertain one. If one started with healthy kidneys, and if the process was unilateral, the prognosis was good. The chances were that such patients would go on to term, and be delivered without complications, and would remain well. On the other hand, there was always a possibility that there would be recurrences either in the puerperium, or subsequently, which would require surgical interference. Among his twenty-five cases there was only one that was operated upon. With regard to the future of these patients, if the process was a one-sided one, occurring in the fifth to the eighth month, running a course in from one to five weeks and then subsiding, the chances were that the kidneys would not become involved and the patient make a permanent recovery. As to the advice to give regarding subsequent pregnancies, he believed that patients should be advised against them so long as there was the slightest evidence of any disease in the ureter; if there was no pus for one year the chances of trouble were small, and the patient might become pregnant and be comparatively safe. The question arose whether the uterus should be emptied, and there were several things to consider. In the first place, after delivery the symptoms subside rapidly; but one could not be certain that the woman would be free from her pyelitis immediately after delivery. He believed it was extremely rare to induce labor before the viability of the child. If the child was viable and the woman still ill with evidences of the disease extending to the other kidney, the interruption of the pregnancy was indicated. In two of the twenty-five patients under his observation the uterus was emptied; in one the child lived; in the other, due to an error in judgment, the uterus was emptied too soon, and the child died. If the child was viable, and if the disease continued in spite of treatment, the indication was to empty the uterus.

Dr. A. Sturmdorf said that pyelitis in pregnancy had been the subject of considerable discussion abroad, and to a more limited extent in this country. The generally accepted data concerning the condition had been most ably set forth in Dr. Cragin's introductory remarks, and Dr. Sturmdorf asked, as Chairman of the Section, the privilege of directing their deliberations along certain lines that required elucidation or revision. In the first place, it was essential to recognize that the pyelitis occurring in the pregnant was in no manner different from pyelitis occurring in the nonpregnant, and the only factors to take into consideration in this respect were the influence of the pregnancy on the condition of the kidney and, reversely, the influence of the complication in question on the pregnancy. Furthermore, the so-called compression theory based upon animal experiments should become obsolete, as there was no analogy between a condition produced by permanent ligature of a ureter and the existence of an impregnated uterus under normal conditions. Pyelitis was observed at a period of gestation when the fetal head was too movable and too far from the pelvic brim to exert compression; on the other hand, the pressure of even hard fibroids did not produce pyelitis without the presence of previously existing infectious foci at some point within or in close proximity to the urinary tract. It must be conceded that pressure could not be exerted upon the ureter without at the same time compressing the pelvic blood-vessels, and in none of the reported cases were symptoms of obstructed circulation noted. Many of the reported cases that came to operation or autopsy presented miliary pus foci in one or both kidneys, thus pointing directly to an infectious process directly or indirectly induced from an immediate or remotely situated focus. So that, aside from the importance of bearing the possibility of the occurrence of a pyelitis during pregnancy in mind, as explanatory of hitherto inexplicable symptoms of infection which might become sufficiently grave to necessitate the termination of pregnancy, one should endeavor to establish lines of demarkation between septic pyelitis, septic pyelonephritis, and multiple kidney abscesses, each of which conditions would demand its own form of intervention. and above all one should interpret the condition as one of a nonrecognized previously existing infection, accidentally brought to light during the course, but *not* as the result of pregnancy.

Dr. Frederic E. Sondern said that he had looked into the literature and had been impressed by the statements made that the condition under discussion was supposed to be infrequent, whereas his laboratory experience was to the contrary. This condition was far more common than generally supposed, and, during the past twelve months, he could recall not less than seven such specimens sent to his laboratory. With regard to the etiology, almost invariably the cases that he knew of were due to the colon bacillus, the organism in many occurring in pure culture. The urinary conditions were quite characteristic, and were the same as described by the men who had written on the subject. There was more or less daily diminution in the amount of urine passed, but without any corresponding increase in the specific gravity. Casts were invariably present. In the tuberculous cases, with apparently the same acute onset, the symptoms were not so severe; the elevated temperature was present, but not the rigors. The impression received from the literature was that the disease was of short duration; but from a study of the specimens he had received it did not appear to have been of such a short duration. While the clinical symptoms might subside, pus remained in the urine for quite an appreciable time, even for months. The improvement did not seem to be a continuous one. There might be a diminution in the bacteriuria and in the amount of pus, as well as in the amount of irritation; then might occur an exacerbation, but not in the clinical symptoms. The first thing to disappear was the bacteriuria; slowly the pus would disappear. The sudden development of acute suppurative nephritis in those cases where the kidney was studded with small miliary abscesses was accompanied with severe clinical symptoms; yet there was little or no evidences of the condition in the urine itself. He recalled an article read recently in which the objection was made to the theory that the colon bacillus

was the cause of the inflammatory lesion; it was claimed that invariably there was a pyogenic infection first. Then injury to the epithelium rendered this a good path through which the colon bacillus entered. It seemed most plausible to consider the acute suppurative condition of the renal epithelium complicating or secondary to pyelitis as caused first by the colon bacillus and not by the streptococcus, the latter not being the original invader.

Dr. E. E. Smith said that in the cases that had occurred under his notice there had been evidences early in pregnancy of a toxemia of the same kind that occurred in gastrointestinal disturbances, showing itself not so much in the increase of indican and sulphates in the urine, but more especially by the occurrence of oxaluria. It seemed to him that the condition of oxaluria showed injury to the tissues of the pelvis especially, thus rendering them more susceptible to suppurative processes. Before the pyelitis came on the urine contained mucus from the pelvis of the kidney, a few pus cells, etc., and in this class of cases one might get a marked acute pyelitis. It was not his experience to find urea diminished in these cases. In pyelonephritis there was an increased amount of albumin. Where the tissues of the kidney were injured one would find a well-marked increase in albumin.

Dr. Lobenstine said that pyelitis was often confused with appendicitis, this confusion occurring twice in his experience; in neither case was it possible to make a diagnosis. In the pyelitis of pregnancy there was a sudden rise in the temperature in most cases, this rise preceding the pain by about forty-eight hours. He believed that a large percentage of the cases would recover under medical treatment. In seven out of nine cases under his observation he was surprised to find some days after delivery a decidedly movable kidney, and he wondered if this had anything to do with the etiology. All of the nine cases occurred on the right side.

Dr. S. Marx did not believe the pyelitis of pregnancy was as rare as generally supposed. He had seen five cases of pure pyelitis complicating pregnancy, and in not one was the diagnosis made, because the condition was really not thought of. The symptoms were as characteristic of appendicular disease as one ever saw. He recalled one of these cases in which the diagnosis was made of appendicitis and ectopic gestation; there was not a characteristic sign in the urine because the ureter was plugged. As to the etiology, he opposed the statements made by Dr. Cragin, that the condition was due to pressure. Many cases he had seen occurred early in pregnancy, when there was no pressure on the ureters. Infection might occur above or below; if above, it was hematogenous; if below, it occurred from a bladder or other lower infection. Very often after delivery it could be traced to catheter infection. In considering the diagnosis one should not forget the possible aid from the introduction of the ureteral probes. An important question concerned the induction of premature labor and the indications for it. Dr. Marx did not think the induction of premature labor was ever indicated if the condition was due to pressure; if it was due to pressure one got a hydronephrosis; the patient should be placed on the side opposite the diseased one, or else in the knee-chest position, throwing the head of the child away from the ureter; this would lessen the danger of a progressive disease of the kidneys. As to the prognosis, the chances for a permanent recovery he believed to be good. The diagnosis of such cases could be made only after several urinary examinations.

Dr. George L. Brodhead said he had found that, as a rule, pyelitis developed between the fifth and eighth month of pregnancy. In all but one of the cases that had fallen under his observation the pyelitis was on the right side. In this case it began in the right kidney and then extended to the left. Two important diagnostic signs related to the pain and the pus. The pain might be acute or moderate. Pus might be found in the urine for weeks, or for months. The treatment he employed was ice-bags, water, and a urinary antiseptic. In all the cases he saw the prognosis was good. With regard to subsequent pregnancies, there could be no doubt that the patient should be advised not to become pregnant while there were any signs of pyelitis present. With regard to the induction of premature labor he felt that if the symptoms were not decidedly improving, and especially if the patient was growing worse, and the disease was accompanied by temperature, he would prefer to empty the uterus, especially if the woman had advanced to the eighth or eight and a half months.

Dr. Brooks H. Wells said he always regarded the pyelitis of pregnancy in the same light as one which occurred in a woman who was not pregnant. In the ordinary cases of pyelitis nearly all occurred on the right side, just as pregnancy. In making a diagnosis, the possibility of mistaking the condition for appendicitis came up, the same in a woman not pregnant as in one who was. The best safeguard was to remember the possibility of a pyelitis. The area of tenderness in pyelitis was not so strictly limited to the area of pain in appendicitis; it occurred with greater or less extent along the site of the ureter on the right side. In four cases of pyelitis in pregnancy that he had seen in only one was it necessary to interrupt labor, and in this case the child was viable. In the other cases the patients were given milk and water and urinary antiseptic, and all made good clinical recoveries. The symptoms, however, persisted in all for a few months, in one case over one year.

Dr. William S. Stone reported one case that fell under his observation in which the clinical symptoms and urinary changes persisted at irregular intervals for several months after labor. Finally a nephrectomy was performed and the kidney was found to be riddled with miliary abscesses. The woman subsequently became pregnant and had a normal pregnancy, except for a few disturbances, such as a trace of albumin, etc. Labor came on three weeks before the time estimated for full term. At times she showed mild toxic symptoms.

Dr. J. Milton Mabbott said he recently saw a case of pyelitis in which there was experienced much difficulty in diagnosing between tuberculous pyelitis, simple pyelitis, and the pyelitis associated with renal calculus. A practical point he wished to bring forward related to the care of the patients during labor and the puerperium, to prevent any possible infection from urine containing bacilli or pus. His own practice was always to have the patient placed in bed or on the douche pan for every act of urination; then with the knees drawn up and separated, to bathe the parts with some antiseptic solution.

Dr. Philander A. Harris said that in such a discussion it should be clearly understood whether they were discussing the subject from the standpoint of the bacteriologist or of the laboratory, or clinically.

Dr. E. B. Cragin closed the discussion. He said that the urine in the ureter was under a very low pressure, 10 mm. of mercury only. That meant that but little pressure was required to dam back the stream. It had been found that any injury to the kidney predisposed that kidney to infection; in pregnancy one had that pressure, and therefore a lowered vitality and more liability to infection. With regard to the onset of the disease and the acuteness of the symptoms, Dr. Cragin said it had been his experience to find that when the temperature was highest and the pain the greatest no change could be detected in the urine; in other words, the ureter was closed at the time of the highest temperature and pain, the acuteness of the symptoms being due to the damming back of the pus in the pelvis of the kidney. With regard to whether this was an ascending or a descending infection, French writers who had done much work on this subject favored the view that it was a

descending infection and through the blood. The fact that the symptoms subsided so rapidly after emptying the uterus favored the supposition that pressure at least had something to do with the pyelitis of pregnancy.

A New Gas and Ether Inhaler.—Dr. Victor C. Pedersen presented this instrument.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, October 15, 1906.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

The Therapeutic Uses of Thyroid Preparations.—Dr. Oliver T. Osborne of New Haven, Conn., stated that the physiological symptoms developed by feeding thyroid were well known. Thyroid extract would increase the rapidity of the heart, increase perspiration, and cause warming of the surface of the body; in other words, it increased the peripheral circulation, lowered the blood pressure, stimulated mental activity even to the point of sleeplessness, caused increased nitrogenous metabolism, and, if in considerable amount or given for a long time, it produced loss of weight. We knew the counterpart of feeding this gland, namely, the symptoms of Graves' thyroid disease. We were also perfectly familiar with the symptoms of absence of function of this gland, as seen in myxedema and cretinism. Dr. Osborne emphasized the fact that all varying increased secretions of the thyroid would give rise to symptoms, and the same was true of all varying decreased secretions. The thyroid gland was easily excited temporarily to increased secretion by emotion, grief, sexual excitement, and for a more prolonged period during menstruation and pregnancy. It was thus seen that the thyroid was a much more active and necessary gland in women than in men; in fact, nearly three-fourths of all cases of disturbed thyroid secretion, either more or less than normal, occurred in women. As age advanced, from fifty on, the thyroid normally began to secrete less than in earlier years. Vasomotor tension therefore increased, arteriosclerosis developed, and we had normal old age, namely, arterial disease, and with it all the phenomena of connective tissue deposits. Finally, as the gland more and more diminished its secretion, senility developed, the skin became dry and eczemas might occur, which were improved by the administration of thyroid extract. Dr. Osborne said that the thyroid gland might have its chemistry so disturbed as to offer a perverted secretion, perhaps neither too much nor too little as a whole, but with its various elements in an abnormal relation to each other. The thyroid, he believed, had something to do with the production or destruction of the red blood corpuscles, as well as with sugar metabolism. Besides the physiological and psychical stimulations of the thyroid gland, certain drugs affected it. Alcohol excited it, and iodine in any form was a stimulant to it. Arsenic, he believed, also stimulated it, which was perhaps the reason that arsenic did good in chlorosis. Phosphorus was probably a stimulant to it, while the prolonged action of such metals as lead and mercury probably inhibited the action of the gland. An excessive meat diet modified the structure, and hence the secretion of the thyroid. It was unnecessary, the speaker said, to discuss the successful use of thyroid preparations in cretinism and myxedema. In ordinary goiter he believed the thyroid would often do harm by stimulating the gland to increased secretion, and perhaps causing a Graves' disease to develop from a simple goiter. In exophthalmic goiter, or Graves' disease, thyroid was positively contraindicated, and would always aggravate the symptoms. In doubtful cases of nervous phenomena, where the question was whether thyroid would help the case or make it worse, he believed that the use of thyroid was contraindicated when there was cerebral excitement, palpitation, progressive loss of weight, sweatings, or flushings. If, on the other hand, the patient was drowsy, apathetic, gaining weight, and the pulse was rather slow, thyroid might be of benefit. There could be no doubt that the proper treatment of Graves' disease was one of the antithyroid preparations or serums. Obesity was well treated by small doses of thyroid, long continued. Large doses he considered dangerous. In high blood tension after the age of fifty he had seen marked benefit from the administration of small doses of thyroid, and the same was true in the asthma of old age. He also had on his records a number of cases of epilepsy treated successfully with thyroid. His attention was first drawn to the use of this preparation in epilepsy by several cases occurring in women at the time of the menopause, the fits showing a suggestive periodicity. He had also found that in disturbances of the thyroid in Graves' disease, a vegetable diet and the withdrawal of meat was advantageous. He thought it advisable to feed thyroid in puerperal insanity, and in the insanity occurring at the menopause. The quality of the thyroid preparation should always be beyond question.

Parathyroids in Physiology and Therapeutics.—Dr. James J. Walsh said it was not long after the discovery of the importance of the thyroid gland, and the consequent widespread interest and careful investigation of it, before it was noticed that there were certain small glandular bodies situated in the neighborhood of the thyroid gland, but readily distinguishable from it in histological structure. These were four or five, at times six in number, usually situated at the lower and outer boundary of the thyroid, two or more on each side, but occasionally occupying a place in the midst of the thyroid substance. They were commonly so closely related to the thyroid gland by anatomical position that it was practically impossible to remove the thyroid without also removing these parathyroids, or at least injuring them so severely as to obliterate their function. After reviewing the work done by Gley, Munk, MacCallum, and others in connection with the parathyroids, and the use of parathyroid material in exophthalmic goiter and Parkinson's disease, the speaker said there seemed to be no doubt that these little glands in the neck were extremely important, and had a significance very different from that of the thyroid gland. It was possible that they might form an important addition or corrective to the secretion of the thyroid. In the near future, very probably, the physiologist would teach us more about them, and then there might be further questions of their therapeutic use. In the meantime they constituted an interesting field for speculation, and doubtless the powdered gland would be used empirically for other diseases with reported good results. Of course a careful analysis of those results would have to be made in order to determine the true significance of the experimental work done.

Physiological Action and Uses of Adrenal Extractives.—Dr. C. E. de M. Sajous of Philadelphia, in his paper on this subject, said the fundamental importance of oxygen in all the functions of the organism, and in the life process itself, hardly needed to be emphasized; and yet the manner in which this gas entered our blood, and its rôle in the tissues might be said to be unknown. The prevailing idea was that the entrance of oxygen into the blood, and the elimination of carbon dioxide, occurred in accordance with the physical laws of diffusion of gases, but a well-known English physiologist, Dr. Pembrey, in an impartial review of the subject published this year, stated that it was impossible to give a satisfactory account of the causes of gaseous exchange between the blood and the alveolar air. Landois, in the last edition of his text-book, ascribed the absorption of oxygen to a chemical process, and adduced various facts which showed that it did not depend on a diffusion of the two gases involved. What was the nature of this chemical process? Bohr and other investigators showed that, contrary to the prevailing view, the oxygen

tension was not greatest in the alveoli, but in the arterial blood, and that pulmonary respiration could only be accounted for by the presence of "a kind of internal secretion," derived perhaps from the alveolar membrane, and capable of actively taking up the oxygen of the alveolar air. The main feature of Bohr's theory, namely, the source and identity of the internal secretion which absorbed the oxygen of the air, had failed to come to light, and it was this function which, in a work published in January, 1903, Dr. Sajous ascribed to the secretion of the adrenals—a conclusion which additional researches had sustained. After briefly outlining a few of the facts upon which this conclusion was based, Dr. Sajous referred to the fact that in his work on "Internal Secretions" he ascribed glycosuria to overactivity of the adrenals, the excessive oxidation in all tissues causing an increase in the production of the agent which converted glycogen into sugar. Another action of adrenal extractives which his views seemed to him to elucidate was the production of arteriosclerosis by their prolonged use, as recently shown by Josué, Erb, von Rzentkowski, and others. Shock was another condition in which adrenal extractives prominently showed their influence on metabolism. Applying this general principle to the internal use of adrenal extractives, a salient feature asserted itself, namely, that whenever they had been found useful in a general disorder it had invariably been in some condition attended with or due to lowered metabolic activity, or adynamia. Solomon Solis-Cohen had introduced the use of suprarenalin in asthma, in cases attended with lowered vasomotor tone, and others had confirmed his observations. The relationship of asthma with the gouty diathesis was well known, and it was also known that this condition was an indication of imperfect nuclein catabolism. Migraine was also related to gout, and Thoma and others had reported cases in which relief followed the use of some adrenal extractive. Hay fever, another disorder ascribed to a gouty diathesis, had been found by Cohen to be influenced favorably by suprarenalin, allowed to dissolve on the tongue. Adrenal extract had been found of value in neurasthenia by many observers, including Huchard. In cardiac disorders it had been highly recommended by several clinicians. Mankowsky specified that the most useful application of adrenal extract was in cardiac weakness and threatening collapse. Floersheim found it effective when our usual remedies had failed. Deeks obtained not only marked improvement in cardiac weakness, but disappearance of attending edema. Boy-Teissier obtained excellent results in cases of weak heart, with general cyanosis and great cardiac dilatation. Finally, in Addison's disease, the vitality was so reduced that we should have in adrenal extract an infallible specific. Some clinicians had obtained marked benefit from its use; others had observed no effect.

Organotherapy from a European Point of View.—Dr. Arnold Lorand of Carlsbad, Austria, took up this phase of the subject. He said that many of the actions of the thyroid could be explained by their iodine constituent. Milk also contained the internal secretions of the different ductless glands, including the thyroid, and thus iodine entered into the composition of milk. The iodine was contained in the colloid substance of the thyroid, and as the thyroid of the infant was very poor in colloid substance the child received the iodine from the mother. Thyroid treatment, with small doses, was harmless, even after the prolonged use of the extracts, providing these were obtained from the fresh glands of healthy animals, not too old, and providing also that the patient was not taking too much meat at the same time. The experiments of Breisacher and Blum on the action of meat upon the thyroid showed that glycosuria could follow the thyroid treatment if much meat was taken. The speaker referred to two such cases that had come under his personal experience, where previously no alimentary glycosuria could be produced after a test dinner with large quantities of carbohydrates. Thyroid treatment could also favorably influence arteriosclerosis, and cirrhotic conditions of the liver and kidneys. Ovarial organotherapy gave favorable results in the nervous symptoms following the menopause and castration. Dr. Lorand said he had invariably seen good results in cases of chronic nephritis by using extracts of the fresh kidneys of the pig. In cases of defective elimination of cooking salt, the speaker said he had seen a considerable augmentation of the same in each case after thyroid treatment, which also increased the elimination of uric acid. In a number of cases he had found that the serum of animals whose thyroid had been extirpated gave excellent results in insomnia.

Dr. Egbert Le Fevre said that the therapeutic uses of the thyroid gland always afforded an interesting study, although he could not say that the results of his work had taken such definite form as those reported by the readers of the papers. Those who were in the practice of general medicine not infrequently met with rather obscure cases, and in such instances some had been induced to try thyroid extract. The benefit resulting from this method of treatment had at times been very pronounced and had led to considerable enthusiasm, in which the speaker said that he himself had been inclined to share, but as time went on he had noticed that this improvement had not been of a permanent character, especially in nervous patients, who were apt to improve temporarily under any new method of treatment. The use of the new instruments of precision for measuring the blood pressure had shown that the thyroid extract had produced a marked fall in cases where the pressure had previously been persistently high. Dr. Le Fevre said he had been much interested lately in the reports of Romberg's clinic upon the effects of the iodides upon blood pressure. It had been shown that when the iodides were given for a long time in small doses they produced a distinct change in the tension of the pulse, due to diminished viscosity of the blood. The speaker said he had seen a number of cases of syphilis in which the withdrawal of the iodides, after their long-continued use in good-sized doses, had resulted in muscular tremor and weakness, and a condition very analogous to that observed in hypothyroidism. It seemed quite apparent that the activity of the thyroid gland had been impaired, or at least modified, by the long-continued use of the iodides. While some patients were temporarily improved, and others permanently, by the use of thyroid extract, the speaker said he had seen cases where harm had been done by the injudicious and persistent use of the remedy, especially when it was given in obscure cases. He had never been able to get any definite results from organotherapy in the treatment of nephritis. In the preparation of all renal extracts, he thought an effort should be made to obtain them from animals which in their diet, etc., were most closely allied to the human species. Otherwise, there was apt to be a wide variance in the physiological properties of the extracts.

Dr. S. P. Beebe referred to the more recent developments in the manufacture of the serum for the treatment of exophthalmic goiter. He said that while much had been heard in regard to the physiology and therapeutic value of the thyroid gland in animals, very little was known in regard to the manner of the action of this serum. It was now a little over a year ago since the first two cases of exophthalmic goiter were treated by this method, but most of the cases of which any definite record had been kept were treated during the past six months. It was therefore impossible, as yet, to make any positive statements regarding its value. Dr. Beebe said that during the hot weather it was almost impossible to make a serum of definite efficiency; this was not only true of the antithyroid serum, but of other serums as well. Serums made in cold weather were much more efficient.

Another fact which we were just beginning to appreciate was the late improvement which sometimes occurred after the serum treatment in exophthalmic goiter. He also referred to its prompt effect in relapses, and mentioned one case where four relapses were readily controlled by single doses of the serum. The relapses, apparently, were much more amenable to the serum treatment than was the original attack.

Dr. C. Am Ende said that eight years ago he began experiments which resulted in the preparation of an extract of sheep's thyroids. The extract contained a substance that apparently acted as an antibody to the cancer toxins, and as an illustration of this fact the speaker presented a case of inoperable adenocarcinoma of the upper rectum and sigmoid flexure in which marked benefit had followed the use of the remedy. He recalled a number of other cases in which it had materially prolonged the life of the patients, and to a certain extent it prevented extension of the malignant diseases through the lymphatics. It also exerted a marked influence in alleviating pain. This was also accomplished by the use of the Roentgen rays, but the combined effect of the rays and the thyroid extract was more pronounced than that exerted by either factor singly.

The discussion was closed by Drs. Walsh and Sajous.

Chicago Medical Society.

At a meeting held October 17, 1906, Dr. William Hessert reported three cases of hemorrhage from the stump following appendectomy. Dr. Albert H. Burr described an easy method of evacuating the contents of the stomach into the duodenum. He likewise spoke of normal lavage without the stomach tube, and gave some therapeutical hints on abdominal gymnastics. He spoke of the conditions under which the stomach contents are retained beyond the period of normal digestion. He described the symptoms of retention, and spoke of the advantages of passing the contents through the normal channel. The method of accomplishing it was by assuming a certain position upon the right side to favor gravitation of the contents to the pyloric end of the stomach. He recommended strong rhythmic contractions of the abdominal muscles upon the stomach to stimulate peristalsis, and said that finally there should be firm fixation of the diaphragm by deep-sustained inhalation while strong abdominal contractions were made. This voluntary reversed emesis was not difficult to learn. The same process was applicable for stomach lavage in a large class of cases where it was indicated for therapeutic purposes, with advantages over the routine use of the stomach tube. He prescribed a series of daily bedside abdominal gymnastics for deep, active massage of all contained viscera, with a view to promoting the activity of the lymph glands and lymph circulation for both therapeutic and prophylactic effects.

Dr. Hugh T. Patrick read a paper entitled "Remarks on a Few Disorders of Sleep." The first disorder described had been called nocturnal palsy, night numbness, sleep numbness, waking numbness, and acroparesthesia nocturna. The patient wakened in the night with one or more extremities numb, tingling, and more or less paralyzed. This paralysis might be complete, but was of short duration. After some minutes of rubbing, slapping, shaking, etc., normal sensation and motion returned and the patient was able to go to sleep again. When the trouble was hemiplegic in distribution it very closely simulated an apoplectic attack without loss of consciousness, and might seriously frighten the patient, as well as give considerable concern to the medical attendant. The causes of this disorder, approximately in the order of their importance, were neurasthenia and general nervousness, malnutrition and general debility, the menopause, rheumatism, cold and wet, anemia, arteriosclerosis, hysteria, tobacco, gastrointestinal disorder, gout, Bright's disease, diabetes, and pregnancy. The next disorder considered was what the author called painful awakenings. In this disorder the patient would waken suddenly with a feeling of intense apprehension or panic, as if something dreadful were about to happen or had just happened. There was apt to be palpitation, tachopnea, generalized tremor, or more frequently a sensation of trembling without visible tremor, sometimes cold perspiration and a feeling of great prostration. As nearly as may be ascertained these attacks had no relation to nightmare or bad dreams. They occurred principally in the course of functional nervous disease, and although most distressing, not to say alarming, to the patient, were entirely harmless, and nearly always disappeared with successful treatment of the general nervous condition. However, sometimes heart disease, Bright's disease, arteriosclerosis, or adenoids stood in a causal relation to the disorder. The author then described different types of what he ventured to call indormescent shocks. They were so called because they occurred just as the patient was falling asleep or immediately after. They might be divided into motor and sensory, although sometimes the two were combined in the same patient or in the same shock. In a very mild degree the motor shock was familiar to everyone, simply consisting of a sharp muscular start or jerk about the time one was falling asleep. The starts in this degree might be called physiological, as nearly every person had experienced them, but they sometimes reached an intensity which made them distinctly pathological. In such a case the sudden muscular contraction might be so violent and so generalized as literally to throw the patient into the air and turn him over in bed, and in some cases these jerks might be repeated ten or twenty times before the patient finally passed into a sound sleep. The sensory shocks were very apt to be related to the special senses. A typical case was that of a neurasthenic patient who was awakened by what seemed to be the discharge of a pistol inside of his head. He was conscious of a tremendous crash, like an explosion, and at the same time felt conscious of a vivid flash of light. He sprang from the bed, was terribly frightened, sat up the rest of the night, and for weeks thereafter retired with great timidity lest there should be a recurrence of the phenomenon. Another patient, a middle-aged woman, had a sensation of having received a violent blow on the head, and she felt certain that someone had struck such a blow. In intense agony she waited for the second, which she felt would follow instantly, but after a time realized that it was purely a sensation and that she had received no bodily harm. Still another patient was suddenly awakened by what seemed to be a great flash of light, and another had a sudden sensation in the epigastrium as if he had received a violent blow in that region. A neurasthenic and hypochondriacal gentleman past middle age was several times awakened by a sound which he likened to a violent and sudden grinding together of two stones, the intensity of the sensation being sufficient to constitute a real pain. Other instances were related, in all of which the disturbance was sufficient to concern, if not greatly alarm, the patient, but the author had never known this particular disturbance to be a symptom of organic disease. The disorder of sleep always disappeared with the disappearance of the nervousness and a return to good general health.

Philadelphia County Medical Society.

At a stated meeting held October 24 Dr. George Erety Shoemaker demonstrated a specimen of "Dermoid Cyst of the Ovary," one of "Ruptured Hematoma of an Oviduct," perhaps an ectopic pregnancy, and one of "Tuberculosis of the Vermiform Appendix." Dr. H. Emerson Wetherill exhibited a simple pocket device for studying atmospheric conditions. Dr. J. Dutton Steele read a paper entitled

"The Clinical Significance of Small Hemorrhages from the Gastrointestinal Tract." He pointed out the value of the test for occult blood in the stools, from both negative and positive standpoints. Care must of course be taken to exclude hemorrhoids and other varicose conditions of veins as sources of hemorrhage. The most common causes of bleeding are ulcer and carcinoma of the stomach or intestine, although occasionally pyloric stenosis and also erosions, as well as such disorders as scurvy and purpura and the like, may give rise to the same phenomenon. Dr. William S. Wadsworth presented a communication entitled "Gunshot Wounds." He discussed the subject on the basis of a considerable experience in the National Guard and in the autopsy room, and he pointed out the varying effects in accordance with the character of the weapon, of the explosive, of the missile, the distance of impact, the structure affected, and a number of other factors. Dr. Augustus A. Eshner read a paper entitled "Paralysis Agitans Without Tremor." He maintained that this disease is not a true palsy and sometimes even the tremor is absent. When present the tremor is made of rhythmic movements, four or five in the second, taking place almost invariably during rest and ceasing, temporarily at least, on voluntary action and also on passive movements, as well as on an effort of the will and on psychic motor impulse, and apparently at times spontaneously. Sometimes it is so little marked as almost to escape observation, but even then the diagnosis of paralysis agitans can be made from the peculiar facies, the stolidity of countenance, the stooping attitude, the rigidity of posture, and the deliberation of movement and of speech. Dr. Eshner reported the case of a weaver, 61 years old, presenting a fixed countenance, stooped shoulders, and a tendency to propulsion. No tremor was present at the first observation, but at a later time slight tremor was appreciable in the thumb of one hand suggestive of the pill-rolling movement, and also tremor of intrinsic muscles of the hand. In this case, as in others like it, the absence of tremor was not constant, and the temporary absence was attributed to restraint through muscular rigidity. The tremor may hypothetically be ascribed to interruption of motor impulses responsible for muscular tone, in consequence of interference by neurogliar hyperplasia with the transmission of nerve-force. The subsidence of the tremor on voluntary movement effort is in turn due to amplification of the tonic motor impulses necessary for the execution of a given movement. Restraint of the tremor by passive movement or by psychic impulses must be considered as reflex.

Philadelphia Neurological Society.

At a stated meeting held October 23 Dr. Carl D. Camp read a paper entitled "Motor Palsy as an Early Symptom of Tabes Dorsalis." He reported illustrative cases and pointed out the relative rarity of the association. Dr. S. D. Ludlum presented a communication entitled "Trauma Preceding Probable Syringomyelia and Tabes," and he demonstrated two patients. In one of them symptoms of locomotor ataxia developed in consequence of a fall from a scaffold at a considerable height, and in the other symptoms of syringomyelia made their appearance following a blow inflicted by the patient upon another person. In each it was a question whether the morbid manifestations and lesions were a result of the injuries or merely came into prominence in the sequence of them. Dr. G. E. Price reported "A Case of Adiposis Dolorosa. The patient, who was exhibited, was a middle-aged woman, who presented enormous enlargement of the lower extremities, with varicose veins and pendulous masses of fat in the upper extremities. The hyperplastic fatty tissue was the seat of pain, spontaneous and induced in various ways. The thyroid gland was not palpable. There was a history of syphilitic infection acquired through the husband. Dr. J. W. McConnell presented "A Patient with Probable Tumor of the brain in the Parieto-Occipital Region." This occurred in a man, about 55 years old, who had had headache, vomiting, unilateral weakness, and impairment of tactile and painful sensibility, astereognosis, with Jacksonian convulsions and homonymous hemianopia. Marked improvement took place under treatment with mercurials and iodides. A similar though less pronounced condition had existed six years previously, and perfect recovery had resulted. Dr. T. H. Weisenburg exhibited a patient presenting "Astereognosis Without Motor or Sensory Involvement." The symptoms disappeared entirely following treatment with mercurials and iodides. Dr. A. Gordon reported "A Case of Bulbar Palsy, with Total Aphemia." The patient, who was exhibited, was a colored woman, 35 years old, who, following an attack of angina, supposed to be diphtheritic, had difficulty in swallowing and in speech, with double facial palsy and weakness of the ocular muscles. The condition was thought to be due to poliencephalitis, although the opinion was expressed in the discussion that it was more probably a peripheral neuritis involving several of the cranial nerves. Dr. Gordon also presented a communication entitled "The Second Anatomical Proof of the Value of the Paradoxical Reflex." He reported the case of a young man having convulsions, with unilateral paresis. The knee-jerk was increased on the paretic side and the Babinski reflex was absent, but on grasping the muscles of the calf firmly between the thumb and fingers of both hands extension of the toes of the foot took place. Accordingly, it was decided that there was irritation of the cortex on the opposite side of the brain and trephining was undertaken, with relief of the symptoms. The discharge becoming retained at a later period, the symptoms returned, including the paradoxical reflex described, and with the restoration of the discharge the symptoms once more disappeared. In another case, one of hemorrhagic pachymengitis, the localization of the lesion was made accurately from the presence of the reflex.

Philadelphia Pathological Society.

At a stated meeting held October 25 Dr. W. M. Late Coplin presented specimens illustrating "Pyloric Stenosis." In one of these the excavation caused by ulcerating carcinoma at the pyloric extremity of the stomach resulted in the formation of a flap that gave rise to occlusion of the pylorus. In the other the pyloric orifice was constricted by carcinomatous infiltration. Dr. S. Leopold presented a specimen of "Carcinoma of the Pancreas." This was scirrhous and unattended with metastasis. There was present a second carcinomatous growth of a different character on the peritoneal surface of the rectum. Dr. D. Riesman exhibited a specimen of "Hypernephroma." The growth came from an elderly woman who had a tumor in the right hypochondrium, at first thought to be a gall-bladder, and later, by reason of the presence of suggestive physical signs, to be tuberculosis of the kidney. Operation was undertaken and the removed kidney was found to be the seat of a hypernephroma. The patient made a satisfactory recovery, but since the operation confirmatory evidence of pulmonary tuberculosis has developed. Dr. H. J. Sommers presented a communication entitled "Detection of Typhoid Bacilli in Milk and Water." He described the difficulty of detecting these germs in the fluids named, largely on account of the more active growth of other microorganisms, particularly the *Bacillus coli communis*. He decided to use milk as a culture medium base, and with appropriate apparatus he was able to isolate typhoid bacilli in a number of instances that otherwise would have yielded negative results. Dr. Joseph McFarland read a paper entitled "Further Observations on Experimental Phagocytosis." With the aid of Dr. L'Engle he endeavored to determine whether there was any relation between the virulence of microorganisms and the activity of phagocytosis, and the results of the observations seemed to indicate that there was no such relation.

Surgical Suggestions.

A New Method of Gastrostomy.—Prof. Tavel of Berne has recently published notes on a new method of performing the operation of gastrostomy. All the older methods of performing the operation have the disadvantages that the opening made closes easily or becomes too small, and that the wall of the stomach is fixed to the abdominal wall. This can be avoided when the stomach is attached to the skin by the intermediation of a loop of intestine that is allowed to retain its mesenteric attachment. This is formed like a new esophagus, with its peristaltic action functionating toward the stomach. The only disadvantage of the operation is that it takes more time than the other method.—*Medical Press.*

Iodine-Benzine Disinfection.—Heusner warmly advocates the routine use of 1-1,000 solution of iodine in benzine as a disinfecting medium for surgical use. It is used as follows: 200 or 300 c.c. of the solution are placed in a disinfected porcelain dish and the dry hands are brushed with this for the space of five minutes. They are then rinsed in a fresh dish with the same solution. The patient's skin is not scrubbed with a brush, but is wiped off with bits of gauze. Finally, the hands and the operative field are anointed with vaseline containing 2-1,000 of iodine. At first this treatment makes the hands somewhat rough and fissured, but even the most sensitive skin soon becomes habituated to it. Bacteriological and clinical tests speak highly in favor of the method.—*Zentralblatt für Chirurgie.*

Aseptic Wound Dressing.—Walter von Oettingen, after extensive experience in the Russo-Japanese War, has come to the conclusion that the aseptic dressing is much preferable to the use of antiseptics in dealing with the wounds of military surgery, and in all probability in private practice as well. His idea is to prevent as much as possible the access of fresh germs to the wound, believing that efforts to kill all of those already present are worse than useless, since the chemicals used, if in proper strength to be effective, must inflict serious damage on the tissues. He accordingly makes no attempt to cleanse the wound or its environment, but as soon as the patient comes under his care paints the entire surrounding skin for a space the size of the palm of the hand with a varnish composed of gum mastich 20.0 g., chloroform 50.0 g., and linseed oil 20 drops. A dry sterile compress is immediately applied to the wound, which is thus completely sealed beyond the possibility of any exposure.—*Zentralblatt für Chirurgie.*

The Treatment of Postpartum Hemorrhage.—A method of controlling postpartum hemorrhage without having recourse to uterine packing, which latter is always difficult for the unassisted practitioner, and involves grave risks of infection, is described by Meyer-Ruegg. The procedure consists in the introduction into the uterus of a pear-shaped, broadly-corrugated instrument of aluminum mounted on an appropriately curved handle and having a width of 5 cm. and a thickness of 3 cm. In cases of impending or actual hemorrhage this metal tampon is introduced into the cavity of the uterus and is used to massage its walls. If atony is marked and no contractions can be induced the uterus may, by means of the instrument, be pressed against the anterior abdominal wall and compressed through this with the left hand. The instrument is allowed to remain in position for twenty to thirty minutes, at the end of which time there is usually little risk of recurrence of the hemorrhage.—*Zentralblatt für Gynäkologie.*

Movable Artificial Eye.—E. A. Hall describes his operation as follows: General anesthesia, insertion of speculum. Circular incision, with sharp-pointed, curved scissors, of sclerotic directly posterior to the ciliary region, and in front of the insertion of the recti. Removal by sharp curette of vitreous retina and choroid. Insertion of speculum blades within the sclerotic, thus exposing the interior of the globe. With mouse-tooth forceps, catch the point of entrance of the optic nerve, pierce the sclerotic with the scissors, and sever the nerve twenty mm. behind the junction, then complete the circuit of sclerotic close to the nerve, and remove the sclero-optic junction. Check hemorrhage, which is usually not profuse. Irrigate with saline. Insert a small gauze drain within the sclerotic, approximate sclerotic and conjunctiva vertically. Withdraw drain after twelve hours. We have now left a zone of sclerotic nourished by a few twigs of the short posterior, and by the long posterior ciliary arteries, with muscular and nervous connections undisturbed. Thus is formed a movable pad upon which the artificial eye is placed. The artificial eye is usually inserted within a week and worn for a few hours each day. The movement of the artificial eye is free up to twenty degrees vertically, and about thirty-five degrees horizontally. This procedure is not applicable in malignant involvement.

STATE BOARD EXAMINATION QUESTIONS.*

REGULAR BOARD MEDICAL EXAMINERS, STATE OF GEORGIA.

April 3 and 4, 1906.

CHEMISTRY.

1. Give the formula of each of five compounds, giving the name in each case, and the dose.
2. Give the name and formula of Epsom salt, Glauber's salt, and Rochelle salt.
3. Mention five mineral poisons, and give the antidote for one of them.
4. Name the nonmetallic chemical elements, which in various combinations are found in the tissues of the body.
5. How may you decide whether a urinary deposit is urates or phosphates?

ANATOMY.

1. Describe the inferior maxillary bone.
2. Name muscles of posterior tibo-fibular group, superficial, and deep. (a) Give origin and insertion of (1) Pectoralis major; (2) External oblique; (3) Sartorius; (4) Triceps muscles.
3. Give course, relations, and branches of external carotid artery. (a) Give blood supply of rectum.
4. Give origin, course, and distribution of great sciatic nerve. (a) Give nerve supply of heart.
5. Describe the stomach.

SURGERY.

1. Give treatment, constitutional and local, of Burns.
2. Name the varieties of fractures. (a) State the cardinal principles in the treatment of fractures.
3. Describe an operation for the radical cure of oblique inguinal hernia.
4. Define hemorrhoids. (a) Give varieties and treatment.
5. Define a chancre. (a) State period of primary and secondary incubation. (b) Treatment, local and constitutional.

MATERIA MEDICA AND THERAPEUTICS.

1. Source of ergot; define its use in obstetrics.
2. Name four preparations of mercury; give dose of each.
3. Source of quinine; for what is it a specific?
4. What is meant by hemostatics? Describe their mode of action; name several of them.
5. Write a prescription for a general tonic with tincture nux vomica and a preparation of arsenic.

OBSTETRICS AND DISEASES OF CHILDREN.

1. How would you manage a shoulder presentation?
2. Differentiate between a five-months pregnancy, ovarian cystoma, ascites and uterine fibroid.
3. What is the Braxton-Hick's sign of pregnancy? How obtained?
4. Under what condition would you be justified in inducing premature labor?
5. What direction would you give the nurse as to care of infant during first week?

PHYSIOLOGY.

1. Describe a white blood corpuscle. Where are they formed? What is their function, and what is their ultimate end?
2. The salivary secretion is derived from what three glands? What is the physiological action of saliva?
3. What are the three motions of the heart, and their cause?
4. What is the volume of air taken in the body in an ordinary inspiration? How is this chemically represented, and how much of the O is absorbed?
5. What is the result of a lesion of the spinal cord in the cervical region? In the sacral region?

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the student with the general character of these examinations and to inspire him with confidence in the result of his trial.

PATHOLOGY.

1. Mention the pyogenic bacteria.
2. Describe the blood changes in pernicious anemia.
3. Give the structural changes which take place in chronic and acute appendicitis.
4. Differentiate between a typhoid ulcer and a tubercular ulcer of the intestines.
5. Describe the process of repair.

GYNECOLOGY.

1. Define menorrhagia and metrorrhagia. (a) Give causes and treatment.
2. Describe an operation for the repair of a lacerated cervix.
3. Give symptoms of carcinoma of the uterus. (a) Treatment.
4. Define retroversion and retroflexion of the uterus. (a) Symptoms and treatment.
5. Give symptoms and treatment of ectopic gestation.

PRACTICE.

1. Define lobar pneumonia. (a) Give symptoms and treatment.
2. Define malaria. (a) Give prophylactic and medical treatment.
3. Differentiate between chickenpox and smallpox.
4. Define measles; point out the most dangerous complications.
5. Differentiate true croup and spasmodic.

OBSTETRICS AND DISEASES OF CHILDREN.

1. Give symptoms, causes, and treatment, of acute mastitis?
2. Give principal causes and treatment of rupture of uterus.
3. Treatment of inertia uteri.
4. Differentiate between diphtheria and the disease with which it might be confounded.
5. Give treatment of bronchopneumonia.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.*

October 9, 10, *and* 11, 1906.

ANATOMY.

4. The collateral circulation is through (1) the internal carotid and vertebral of one side with those of the other, through the circle of Willis; (2) superior thyroid with inferior thyroid; (3) deep cervical of superior intercostal with princeps cervicis of occipital; (4) superior thyroid, lingual, facial, occipital, and temporal branches of external carotid, with corresponding arteries of the other side.

PHYSIOLOGY.

1. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) anabolic, or constructive, and (2) catabolic, or destructive.
2. When, in the small intestine, by the action of the pancreatic enzyme amylopsin, it has been entirely converted into maltose and dextrose.
3. The portal system of veins begins and ends in capillaries. Its function is to carry to the liver blood loaded with material absorbed from the contents of the stomach and intestines.
4. The functions of the liver other than the secretion of bile are: (1) the formation of glycogen, (2) the formation of urea and uric acid, (3) the manufacture of heat, and (4) the conversion of poisonous and harmful into inert material.
5. The changes take place in the capillaries of the lungs, and are: (1) the giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor.
6. The functions of the stomach are: (1) to receive the food after mastication and deglutition; (2) to secrete the gastric juice, which can act upon the food after it has entered the stomach; (3) by means of its muscular movements to blend and incorporate the gastric juice with the food it has received; (4) to absorb such parts as are ready for absorption.
7. The valveless veins are: the venæ cavæ, hepatic veins, portal vein and its branches, renal, uterine, ovarian, pulmonary, cerebral, spinal, and umbilical veins. The sinuses of the skull and very small veins are also without valves. These veins, not being liable to pressure, do not require the action of the valves, the chief function of which is to prevent a reflux of blood back towards the capillaries.
9. The function of the sympathetic nervous system is to supply (1) the muscles of the vascular system, by means of the vasoconstrictor and vasodilator nerves, also the accelerator and inhibitory nerves of the heart; (2) the muscles of the various viscera; (3) various glands, such as the lacrymal and parotid glands.
10. Proteids, carbohydrates, fats, and water are all essential to health.

HISTOLOGY AND EMBRYOLOGY.

3. The lymphatic circulation is, strictly speaking, not a circulation at all; since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.
4. About the end of the third month of fetal life the primitive epidermis, over the end of the digits, thickens, and the nail area is outlined by a furrow. The root of the nail is then marked by an ingrowth of the rete Malpighii. A little later, the upper cells of the Malpighian layer become covered with granules, which eventually become hardened to form the nail substance; at the same time the stratum lucidum cells increase in number, and help to form the body of the nail. Last of all, the free edge of the nail is formed by the shedding of the stratum lucidum. The growth of the nail is caused by the addition of cells at the posterior margin; it gains in thickness by additions from the stratum mucosum at the lunula.
5. Peyer's patches are large, oval groups of lymph follicles, closely packed together, and held in place by adenoid tissue. They are chiefly found in the ileum.

CHEMISTRY AND TOXICOLOGY.

1. An acid is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base. A base is a substance which can enter into double decomposition with acids to produce a salt and water.
2. Valence is the combining power of an atom of an element as compared with that of an atom of hydrogen. Calcium is bivalent; sodium and potassium are univalent.
3. Ammonia is prepared by heating a solution of ammonium hydroxide:

$$NH_4HO = NH_3 + H_2O$$

4. An anhydride is an oxide capable of combining with water to form an acid.
5. Ferments of the body are: (1) proteolytic, *e.g.* trypsin; (2) amylolytic, *e.g.* ptyalin; (3) steatolytic, *e.g.* steapsin; (4) inverting, *e.g.* invertin; (5) coagulating, *e.g.* milk curdling ferment.
6. Gastric juice consists of ninety-nine and a half per cent. water, and half of one per cent. solids. It contains hydrochloric acid, pepsin, a curdling ferment, mucin, salts, and water. The amount of free hydrochloric acid is about two parts in a thousand. Tests for free hydrochloric acid: (1) Add to a few drops of filtered gastric juice one drop of a solution of dimethyl-amido-azo-benzol; a cherry red color develops. (2) The reagent is prepared by dissolving two grams of phloroglucin and one gram of vanillin in 100 cc. of 90 per cent. alcohol; then place an equal number of drops of this reagent and of gastric juice (filtered) on a porcelain dish, and allow the fluid to evaporate slowly; a rose tint appears at the edge.
7. Symptoms of poisoning by bichloride of mercury are: a burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; bloody stools, also salivation may occur.

Treatment: the antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

8. In opium poisoning there may be three stages: (1) a period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused, the reflexes are abolished, the pupils are very contracted,

*The questions were published in the issue of November 3.

the pulse is slow and irregular, and the respirations are infrequent and shallow.

In alcoholic poisoning the pupils are not contracted, the respirations are about normal, and the skin is cooler than in opium poisoning.

9. In cocaine poisoning there will be found pain and fullness in the head, pulse first quick, later feeble and slow, extremities cold. The symptoms are not constant.

10. The continuous use of acetanilide may give rise to decrease in the number of red blood cells; the face is livid and covered with perspiration, the respirations become slow and shallow, the pulse soft, compressible, and gradually weaker.

Treatment: stop further administration of the drug, then support the patient by stimulants, warmth, and strychnine.

BACTERIOLOGY.

1. Bacteria are unicellular organisms of vegetable nature, devoid of chlorophyl, and multiplying by fission. They are recognized by their shape, size, mobility, grouping, growth, and behavior to cultures and staining reagents. The chief culture media are: milk, blood serum, bouillon, gelatin, agar, potato. The conditions favorable for their growth are moisture, temperature of between 10° and 40° C., nutritive material in the shape of decomposable organic matter, a medium of neutral or faintly alkaline reaction, and rest. Bacteria enter the body through the abraded skin or mucous membrane, or through the respiratory and alimentary tracts.

2. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

3. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

4. Ptomaines are the putrefaction products of dead animal tissues or fluids.

Toxins are the products of pathogenic bacteria or of ptomaines or leucomaines, and are actively poisonous.

Toxoids are toxins whose poisonous properties have been reduced or modified.

An antitoxin is a substance formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

An antitoxic unit is the quantity of antitoxin, which, on being inoculated into a guinea pig weighing 250 grams, will neutralize one hundred times the lethal dose of toxin.

5. A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it, and placed on a clean cover slip, and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

The dose of diphtheria antitoxin is from 2,000 to 3,000 units to be injected as soon as possible, and, if necessary, to be repeated in twelve hours; in severe cases it may be repeated earlier. In laryngeal and severe pharyngeal cases a larger dose may be used, up to 5,000 units. The immunizing or prophylactic dose is from 200 to 500 units.

SURGERY.

1. Local anesthesia can be caused by applying a mixture of salt and ice, or by spraying the part with ether or with ethyl chloride. Cocaine hydrochloride, in watery solution of about 5 to 8 per cent., can also be applied to a mucous surface, or in a one per cent. solution it can be dropped into the eye. The same drug can be used hypodermically in solution of from one to four per cent., but it does not act on inflamed tissues. When injected into a finger or toe, its action can be increased by the application of a tourniquet, which prevents the solution from being carried away in the blood current. Hypodermic injections of sterile water are said to have the same effect as those of cocaine.

2. Sepsis is a condition due to the entrance and multiplication of bacteria in the body, or by the absorption of their products. The stages are (1) that of septic fever, with rapid rise of temperature, remitting each morning, pulse full and rapid, anorexia, furred tongue, dry skin, constipation, scanty, high-colored urine, headache; (2) hectic fever, due to retention of discharges, with fever, flushed face, anorexia, tongue dry and red, diarrhea, profuse sweating, urine loaded with urates, and tendency to formation of bedsores; (3) in long-standing cases amyloid disease may follow, especially when there is a long-continued discharge; albuminuria and diarrhea are commonly present in this stage.

4. The indications for inguinal colostomy are: (1) congenital absence of the rectum when incision by the perineal route fails to reach the intestine; (2) chronic obstruction of the large intestine, which cannot be relieved by other means; (3) volvulus of the sigmoid flexure which cannot be otherwise reduced; (4) cancer of the rectum when a radical operation is inadvisable; (5) as a preliminary operation to excision of the rectum.

6. The chief complications of fracture are: compound fracture, injury to blood-vessels, gangrene, degeneration and contraction of muscles, stiff joint, atrophy of limb, suppuration, injury to nerves, fracture into joint, dislocation, septicemia, fat embolism, pneumonia, and delirium tremens.

GYNECOLOGY.

1. Laceration of the cervix may cause hypertrophy, elongation, sclerosis, cystic degeneration, or carcinoma of the cervix; subinvolution, or displacements of the uterus, also endometritis. Other results may be pain on walking, on defecation, or during coitus; sterility or abortion; headaches, backache, neuralgic pains, neurasthenia, indigestion, constipation.

2. Lacerated perineum may be followed by local tenderness, irritable scar, reflex disturbances, subinvolution of the uterus, rectocele, cystocele, prolapse of the uterus, and incontinence of feces.

3. Vaginismus is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. Its causes are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, carunculæ myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The treatment consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a five per cent. solution of cocaine will relieve the hyperesthesia and allow of coitus.

4. The sources of streptococcic poisoning in the puerperium are the hands of the physician, nurse, midwife, or of the patient herself; unclean instruments and catheters; coitus during the time immediately preceding labor; contact with secretions from wounds of any kind, no matter where situated; general unhygienic surroundings, and contact with a patient suffering from scarlet fever or erysipelas on the part of any one attending on the woman. The percentage of such cases will depend on the care exercised by doctor, nurse, etc.; when infection does occur, it is generally streptococcic infection, either pure or mixed with other germs.

OBSTETRICS.

1. In external pelvimetry four measurements are generally taken: (1) between the anterior superior spines of the ileum, normally about ten and a quarter inches; (2) between the external edges of the iliac crests, normally about eleven inches; (3) between the heads of the two great trochanters, normally about twelve and a quarter inches; and (4) between the spinous process of the last lumbar vertebra and the upper margin of the anterior surface of the symphysis pubis, normally about eight inches.

2. It was formerly held that pregnancy had a beneficial effect upon tuberculosis, that the mother was likely to improve as long as the pregnancy lasted, though she might rapidly fail after the birth of the child. The more recent view is that pregnancy exercises a harmful effect; that pregnancy, labor, and lactation only weaken the patient, lower the vitality still further, and hasten the end.

3. The patient should be advised to avoid indigestible or very highly seasoned articles of food; her diet should be

nutritious and sufficient. In patients who have previously had unduly heavy children it would be well to restrict the carbohydrates and fluids during the last two or three months of pregnancy. The tendency to constipation, which may be increased during pregnancy, should be overcome by laxative foods or fruit.

PATHOLOGY.

1. The etiology of hyaline degeneration is somewhat obscure; it is said to be caused by infections and intoxications, such as lead, alcohol, and syphilis. The seats are: the blood-vessels in the brain, lymphatic glands, voluntary muscles, and ovaries. Aneurysms, sclerosed arteries, the heart in endocarditis, and gummata may also undergo hyaline degeneration.

2. Normally, the blood contains about 0.1 per cent. of grape sugar, which is chiefly derived from the carbohydrates in the food, but also by a splitting up and rearrangement of the elements of the proteids, and possibly also from the fats. This and other changes are supposed to take place in the liver, which, together with the muscles, converts the sugar into glycogen, and also acts as a storage place for the glycogen. The glycogen is changed again into sugar and passed into the blood, which is thus kept supplied with its proper amount. In diabetes this arrangement becomes disturbed, with the result that some of the sugar delivered to the blood is not utilized. According to Tyson, this may be brought about in several ways: (1) It may be that the glucose arising by a reconversion of the glycogen stored in the liver is contributed to the blood too rapidly to be oxidized; (2) It may be that, although the glucose is delivered in normal quantity, it is still not consumed because of some defect in the oxidizing mechanism, some deficiency in the glycolytic ferment; (3) It may be that the glucose arising from sugar and starch digestion in the intestine is not first converted into glycogen as in health, but passes directly through that organ to the vena cava too rapidly or in too large quantity to be utilized, or lacking some molecular quality which permits its oxidation.

3. In extreme cold the skin is pale and waxy, with irregular dusky, reddish patches; the superficial parts are bloodless, while the viscera, including the brain, are congested; the heart and large vessels leading from it are full of blood, and the blood is of a brighter red color than usual. In extreme heat, the lesions are great congestion of the viscera, early rigor mortis and putrefaction, the red blood corpuscles are broken up, and otherwise altered in appearance, there is also coagulation of the proteid matter in the tissues, and the kidneys have a reddish-brown color.

7. Fibrinous pneumonia is the same as lobar pneumonia; catarrhal, is the same as lobular or bronchopneumonia; purulent, is any form of pneumonia in which pus is formed; fibrinous pneumonia is the same as interstitial pneumonia, and is often called fibroid phthisis, or cirrhosis of the lung.

8. Caries means molecular death and disintegration of bone, attended with suppuration. Necrosis implies that a portion of bone has died *en masse*, molar death of bone. These two terms are used in regard to bone, in the same way that ulceration and sloughing are, with regard to the soft tissues.

PRACTICE OF MEDICINE.

1. The remote effects of syphilis of the nervous system are: Mania, melancholia, paretic dementia, pseudoparesis, myelitis, meningomyelitis, paraplegia, hemiplegia, locomotor ataxia, general paresis, neurasthenia, hysteria, epilepsy and neuralgia.

6. In duodenal ulcer the pain is apt to be more to the right and to occur at an interval of two or three hours after meals; the hemorrhages will be intestinal, and the blood will be passed by way of the bowels, and not vomited. In many cases the symptoms are identical with those of gastric ulcer.

7. In typhoid fever there is a dull and apathetic expression, the cheeks may be flushed, the tongue dry, and the teeth covered with sordes. In tetanus the jaws are firmly closed, the corners of the mouth are drawn up, and the forehead is wrinkled. In exophthalmic goiter there is a staring expression, accompanied with more or less protrusion of the eyeballs.

9. Streptococcic infection of the throat presents symptoms that are apt to be more severe than those of diphtheria. The temperature runs as high as 104° to 106°, but the only sure test is in the absence of the Klebs-Loeffler bacillus.

EYE, EAR, NOSE, AND THROAT.

2. In the condition known as the Argyll-Robertson pupil, the pupil responds to accommodation, but not to light. It is found in locomotor ataxia, general paralysis of the insane, and sometimes in cerebral syphilis.

MEDICAL JURISPRUDENCE.

1. Medical Jurisprudence is the application of the knowledge of any of the branches of Medicine to the problems and requirements of the law.

4. According to Taylor, the term insanity is applied to "those states of disordered mind in which a person loses the power of regulating his actions and conduct according to the ordinary rules of society. In all cases of real insanity the intellect is more or less affected."

5. Malpractice includes any act, whether willful, or through negligence or ignorance, by which a physician or surgeon causes a person under his care to suffer death or unnecessary injury. The physician is not supposed to guarantee a cure, but is expected to do his best to bring about a cure.

HYGIENE AND PUBLIC HEALTH LAWS.

1. Hygiene is the science and art of all that tends to the maintenance and improvement of health, the prevention or shortening of the duration of diseases, and the prolongation of life. Health laws are such regulations, ordered and enforced by the proper powers in a community, as deal with the subjects comprehended under hygiene, and include the arrangement and building of houses, schools, etc., their ventilation, water supply, lighting, and the removal of refuse and excreta; the regulation of dairies and slaughter-houses, the management of infectious diseases, the regulation of trades, the supervision of nuisances, and the disposal of the dead.

2. Impure water may cause typhoid fever, dysentery, diarrhea, indigestion, goiter, vesical calculi, cholera, yellow fever, scarlet fever, diphtheria, tapeworms, and lead poisoning. Impure milk may cause tuberculosis, scarlet fever, diphtheria, typhoid fever, and cholera.

3. CO_2, organic matter, or crowd poison may accumulate. As an adult is supposed to require 3,000 cubic feet of fresh air per hour, a child may be supposed to require, say, 2,400 cubic feet per hour, or forty cubic feet per minute.

MATERIA MEDICA AND THERAPEUTICS.

1. By the empirical use of remedies is meant the employment of them, because it has been found by experience that they are of benefit in conditions similar to the one under treatment; *e.g.*, colchicum in gout, opium to relieve pain. By the intelligent employment of remedies is understood their use based upon a knowledge of the physiological action of the drug and a further knowledge of the pathological condition present; *e.g.* the use of digitalis in mitral lesions of the heart.

2. Among the so-called remedies now relegated to a judicious oblivion, may be mentioned the use of quintine in typhoid, potassium chlorate in diphtheria, large doses of creosote in pulmonary tuberculosis, bleeding for nearly everything, methylene chloride as an anesthetic, Condurango for cancer, and sarsaparilla for syphilis.

3. Hypnotics are agents used to induce sleep. The two classes into which they may be divided are: (1) those which relieve pain and produce sleep, and (2) those which will produce sleep, but will not relieve pain. Opium is an example of the former class, and chloral of the latter.

4. Anthelmintics are drugs used for the purpose of removing intestinal worms. Vermifuges cause the expulsion of these worms, and vermicides destroy them. The parasites against which they are directed are: (1) the round worm (*Ascaris lumbricoides*); (2) the tapeworm (*Tænia solium, T. saginata,* and *Bothriocephalus latus*); (3) the seat worm, or round worm or pin worm (*Oxyuris vermicularis*); and (4) *Ankylostoma duodenale.*

Conception During the Existence of Amenorrhea.—Louis Bricout has made a careful study of this subject, and has reached the conclusion that amenorrhea is far less frequent during lactation than is generally admitted. Conception during this amenorrhea is very frequent. As conception often occurs during lactation it may be surmised that in spite of the absence of menstruation, ovulation continues in a normal manner. Bricout cites an extremely curious personal observation. A woman thirty-five years old had had within fifteen years seventeen pregnancies. Thirteen of the children were born at term; there were four abortions. In all of these pregnancies conception had taken place during the amenorrhea of lactation, without the re-establishment of menstruation. In essential amenorrhea, that which is not connected with any pathological alteration of the genital organs, conception is far more rare, although it is sometimes observed.—*Journal de Médecine et de Chirurgie Pratiques.*

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Missouri reciprocates under certain conditions, with Indiana, Michigan, Nevada, Maine, Minnesota, Delaware, Iowa, Kansas, Colorado, Kentucky, Wisconsin, Wyoming, and the District of Columbia. A licentiate living in either of these States who desires to secure a license in Missouri to practise medicine must be able to comply with the following rules: (1) That a certificate of registration showing that an examination has been made by the proper board of any State, on which an average grade of not less than 75 per cent. was awarded, the holder thereof having been at the time of said examination the legal possessor of a diploma from a medical college in good standing in the State where reciprocal registration is sought, may be accepted in lieu of examination, as evidence of qualification: Provided, that in case the scope of said examination was less than that prescribed by the State in which the registration is sought, the applicant may be required to submit to a supplemental examination by the board thereof in such subjects as have not been covered. (2) That a certificate of registration or license, issued by the proper board of any State, may be accepted as evidence of qualification for reciprocal registration in any other State: Provided, the holder of such certificate had been engaged in the reputable practice of medicine in such State at least one year: Provided, also, that the holder thereof was, at the time of such registration, the legal possessor of a diploma issued by a medical college of four years' requirements in good standing in the State in which reciprocal registration is sought, and that the date of such diploma was, prior to the legal requirements of the examination test, in such State.

Georgia.—A bill which has been introduced into the Legislature providing that the right to practise medicine should be granted all products of incorporated medical colleges in this State, without the necessity of passing the State board examination, was killed in committee.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending November 10, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	319	163
Diphtheria	290	39
Measles	57	2
Scarlet Fever	84	3
Smallpox	—	—
Varicella	36	—
Typhoid Fever	138	20
Whooping Cough	31	6
Cerebrospinal Meningitis	10	10
Malarial Fever	.....	.....
Totals	965	243

Basic and Acid Equivalents in the Urine in Physiological Conditions.—Arturo Campani studied the oscillations in the curve of acidity in the urine in various ages, sexes, and physiological conditions. He gives us his results in the following conclusions: As to the time of day, the urinary acidity is at its maximum in the afternoon, its minimum in the morning, between the two in the night; the basicity is least in the night, greatest in the morning, and is high throughout the day. The absolute amount of acids and bases is smallest in the night, greatest during the day. This is due to the food ingested; during digestion the acids and bases are increased; after digestion is over they are reduced again. The vegetables increase most the amount of the bases. The albuminoids reduce them. Acidity and basicity are least in infancy, greatest in the prime of life, lessened in age. In women the excretion of acids and bases is greater than in man; in menstruation the excretion of acids is increased; pregnancy produces no change except lessened diuresis.—*Giornale Internazionale della Scienze Mediche.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending November 9, 1906:

REPORT OF ONE HUNDRED CONSECUTIVE LAPAROTOMIES; WITH SOME GENERAL OBSERVATIONS, AND A SPECIAL REFERENCE TO APPENDICITIS.

BY VICTOR F. MARSHALL, B.S., M.D., AND
EDWARD W. QUICK, M.D.,
APPLETON, WISCONSIN.
SURGEONS TO ST. ELIZABETH'S HOSPITAL.

IN offering this analysis of one hundred recent consecutive laparotomies we wish to emphasize certain facts that are already well known to the profession, and, if possible, to add some data that may assist in clarifying some mooted questions in operative surgery. The cases come under the following heads: (1) Acute Appendicitis, twenty-one cases; (2) Chronic Appendicitis, eighteen cases; (3) Gallstones, five cases; (4) Cholangitis (Cholecystitis), two cases; (5) Gastroenterostomy, two cases; (6) Intestinal Obstruction, two cases; (7) Ectopic Pregnancy, two cases; (8) Hysterectomy (Abdominal), four cases; (9) Large Ovarian Cyst, two cases; (10) Miscellaneous operations on uterus and adnexa, including pyosalpinx, small ovarian cyst; prolapse ovary and displacement of uterus, thirty-one cases; (11) Hernia—Inguinal, six cases; Femoral, two cases; Ventral, three cases. The mortality in this series was 2 per cent. One patient operated upon for acute appendicitis died the second day. This case will be discussed under indications for operation in acute appendix disease. In the second case, a hysterectomy for fibroid weighing 12½ pounds, the patient died thirty-six hours after operation from shock. This patient had been confined to bed for four months and was exsanguinated.

We have endeavored in doing intraabdominal work to use the smallest incision possible and to enlarge it to give good view and ample room for whatever manipulations are necessary. In deep and difficult work no incision is large enough that will not admit the whole hand. That operative rapidity is an element of success there is no doubt, for the inconveniences of anesthesia, the chances for infection, the exposure to the air, and the drying of the anatomical parts exposed during the course of an operation are all factors which are unfavorable and increase in importance in geometrical ratio with the duration of the operation. Many simple appendicitis operations are completed in fractions of an hour, while others with extensive adhesions may consume more than an hour. Facility of technique is cultivated without especial thought as to the exact number of minutes used in the performance of the operation.

In this series of cases we have used the following procedure for closing the abdominal wall, employing the Bartlett process catgut for buried sutures: The peritoneum is closed separately, bringing the serous surfaces together to prevent, as far as possible, any adhesions of the abdominal viscera to the line of incision. Whenever necessary, the muscles are approximated with one or more sutures loosely tied. We think the proper approximation of the fascia is the keynote to the prevention of postoperative hernia, and our technique is to overlap the fascia according to the method popularized by Noble. If adipose tissue is excessive, sutures are placed in it. In small incisions the subcuticular stitch of heavy silkworm gut is used. The cosmetic effect even upon the patient's abdomen is not to be ignored, for ugly scars and stitch marks are offensive. Unless some special indication arises, the wound is not inspected until the time of removal of suture or sutures. Exception, of course, is to be made in those cases in which there is possibility of suppuration. In such cases the figure-of-eight suture is used, so that one or more may be removed if necessary to establish peritoneal drainage.

In the series peritoneal drainage was instituted in eleven cases, of which nine were drained by the insertion of a rubber tube. The methods of employing the tubes were as follows: (1) Simple fenestration and wrapping with gauze; (2) split tubes with gauze wicks; (3) cigarette drain made with alternate layers of gauze and dental rubber. The Mikulicz drain was used in one case of ovarian cyst in which there were dense adhesions and persistent hemorrhage—Case No. 40. We will refer to this later under intestinal obstruction. One, Case No. 15, was drained by ½-inch gum rubber tubing, fenestrated, from the abdominal wall externally through vagina. This case was an infected ecoptic pregnancy, which came to operation with a temperature of 103° and a pulse of 130.

In several evidently similar cases we were somewhat in doubt as to the advisability of employing drainage, and in these cases we found the progress quite as satisfactory as in those in which drainage had been employed, and our tendency is to use drainage less often than formerly.

During our student career ten years ago the recognized teaching was to keep all laparotomy patients quiet in bed for twenty-one days. We are following, however, more recent thought in this connection, and have shortened this irksome period markedly. In all simple laparotomy cases with small incisions, and in which extensive work is not done upon the viscera, the patients are placed in sitting posture upon the third or fourth day and permitted to be up upon the sixth day, usually leaving the hospital before the tenth day. The other cases are a law unto themselves, depending upon their general condition. Great latitude is permitted patients as regards movement in bed after the first day.

As soon as the vomiting ceases following anesthesia, and in those cases in which no vomiting has occurred, water is permitted by mouth in small quantities at frequent intervals. An exception to this is made in those cases in which the operation

involves the upper portion of the gastrointestinal tract. The withholding of water in times past from laparotomies has been the cause of untold suffering. We believe this practice was founded largely upon error. What is absorbed freely by the duodenum and should be given freely after vomiting has ceased. One point which stands out prominently is the fact that in but a very small percentage of cases was it necessary to use hypodermic injections of morphine to control pain. It has been our custom to use primarily aspirin in 10- to 15-grain doses, and if this is not effective, codeine sulphate gr. one-half hypodermically is given; if both fail to produce rest and quiet, morphine is given.

In ninety-four cases anesthesia was induced by ether, the open method being used. In the remaining six cases chloroform was used for the following reasons: In three cases there was present at the time of operation a mild bronchial affection; in three cases the operation was performed by lamplight in homes. A decided preference is given to ether for anesthesia, and, whether well founded or not, we shall act upon the belief for the present that ether is a safer general anesthetic than chloroform, due regard being paid to the respiratory, cardiac, and renal lesions. All anesthesias are preceded half an hour by a hypodermic injection of morphine gr. 1/4 and atropine gr. 1/100.

One of the routine rules followed in the after-treatment of our patients is the use of a rectal injection of eight ounces of physiological salt solution every three or four hours until all symptoms of shock and the feeling of thirst have disappeared. Hypodermoclysis was used in four cases. Intravenous transfusion was not found necessary in any of the cases of the above series. Whenever tympany became a source of discomfort to the patient before the bowels had freely moved, the rectal tube was inserted high to facilitate the passage of flatus, which usually gave immediate relief.

In all of the cases twenty-four hours after operation calomel was given in 1/10 gr. doses, repeated hourly until one grain had been given, followed in two hours after the last dose by two drams of magnesium sulphate. Exception to this is made, of course, in major-operations on the gastrointestinal tract. When an unsatisfactory result occurred, a high rectal enema of magnesium sulphate, glycerin, and water, in the usual proportion of 2, 4, and 6 ounces, respectively, was given.

During the day preceding the operation the patient is given light diet and allowed an abundance of good water and a warm general bath. A mild cathartic in the form of castor oil or magnesium sulphate is also given this day, followed by an enema the morning of the operation. Castor oil is generally given in the foam of beer or with extract of malt. The field of operation is prepared the evening before by first shaving, and by thorough washing with green soap and water, and then the application of soap poultice to the abdomen until entrance into operating-room. The abdomen is then washed once more with a soft brush or gauze and soap, followed by sterile water, and this in turn by ether, alcohol, and corrosive sublimate one part to one thousand. In emergency operations the preliminary preparation was necessarily omitted, and in this series we have noted no difference between the two methods in obtaining primary union. Four sterile towels are placed about the field of operation with just enough space exposed. Over the towels is placed a sterile sheet with an opening sufficient in size to do whatever is necessary. Upon completion the wound, unless drainage has been instituted, is sealed with gauze and collodion, which is not removed until the time of removal of suture or sutures. The hands are prepared by washing in an abundance of soap and water, using a brush which is not coarse. After thorough washing for fifteen minutes the hands are immersed in corrosive sublimate, one part to three thousand, and kept there several minutes. After washing again in sterile water and drying with a sterile towel, dry rubber gloves are put on. The rubber gloves are sterilized with dressings in the autoclave, and in the past two years that we have been using this method of sterilizing them we have as yet found no reason to change. There were no cases of stitch abscess when drainage was not necessary. Eight patients were operated upon in private houses, with no deaths, while the remaining ninety-two were operated upon in the hospital, with two deaths. The above number is too small to use as a legitimate base of comparison.

One patient, Case No. 40, aged twenty-two, had a somewhat stormy convalescence. In removing a large left ovarian cyst which was closely adherent to the pelvic floor, uterus, and bowel it was necessary to use a Mikulicz drain to check persistent hemorrhage. The drain was removed without difficulty six days later, and all augured well for a speedy convalescence until the morning of the twelfth day, when some symptoms appeared of intestinal obstruction, vomiting occurring after a breakfast of light cereal, toast, and coffee. During the night previous, however, she complained of some abdominal distress, as of "something pulling." As both the temperature and pulse were normal and nothing was found at the time to account for this sudden emesis, the nurses were directed to watch the case carefully and notify us of any change. Thinking the food had produced this sudden change, liquid nourishment was ordered for the day. Next day, the thirteenth day after operation, she vomited again an hour before the regular time for breakfast. The matter consisted of nothing more than stomach fluid. The stomach was now thoroughly lavaged and liquid food ordered continued. The bowels moved thoroughly shortly after the lavage. The following day the conditions were about the same, with the exception that there was no emesis until near noon, when vomiting again appeared, and recurred at intervals of half to one hour, first of stomach secretions, and later of a material with fecal odor. As we were occupied with other work outside the city, we did not see the patient until 5 o'clock, when, after examination, intestinal obstruction was diagnosed, due no doubt to angulation of the bowel from adhesions, and we decided upon immediate reopening of the abdomen. This was done with little difficulty and the obstruction was found to be caused by the omentum adhering quite firmly to the raw surface upon the posterior aspect of the uterus and floor of pelvis, about which the bowel had become angulated. The omentum was divided between two ligatures and the abdomen was closed, after which convalescence progressed rapidly, the patient leaving the hospital ten days after the second, or twenty-four days after the initial laparotomy.

The series presented eighteen cases of chronic appendicitis. Some were operated upon after a single attack in which local tenderness persisted, several after the second attack, and a few after a dozen or more. We do not advise operation after a single attack has subsided, but do invariably after the second. In no case has there been persistence of symptoms. In

several cases the appendices had such an absence of anatomical change that we doubted the correctness of the diagnosis, but the course of events demonstrated the efficacy of the operation. We are continually on guard against those patients with neuroses who imagine themselves suffering with the most common diseases in the community. Of acute appendicitis there were twenty-one cases. The time of operation varied from a few hours after the onset of symptoms to cases in which definite abscess was of several days' standing. We are without equivocation in the camp with those surgeons who believe there is but one indication for operation, and that is the positive diagnosis that acute appendicitis exists. To this we make one exception. Cases seen in consultation in which no abscess has formed and in which the patient is decidedly better, as evidenced by his own word and the facts recited by the attending physician, in short, where convalescence is progressing satisfactorily and patients are on the mend, we do not operate. However, we are not disposed to quarrel with our colleagues who do not make this exception.

No case is considered hopeless or too sick to stand an operation so long as the radial pulse can be felt. Early, intermediate, and late operations, as defined by hours and days, are terms that should be relegated to the attic of worn-out and obsolete medical terminology. The virulence of the infection and the condition of the lumen of the appendix with respect to drainage determine the time of gangrene and rupture. The only case lost was that of a young woman of twenty-five years. She was seen one morning and gave a history of diarrhea for two days, with diffuse abdominal pain of a mild character. There was slight tenderness over the appendix. Pulse 90, temperature 99°. She was seen again at 5 P. M., when the temperature was 102°, pulse 96, with marked rigidity on the right side. Appendicitis was diagnosed and immediate operation advised. The family wanted consultation, and the patient did not go on the operating table until 1 A. M. the following morning. When the peritoneum was incised a beginning peritonitis presented itself. The appendix was immediately accessible and was removed. A drainage tube was inserted. The patient died twenty-four hours later of septic peritonitis. We believe she would have died without operation. Other cases of the series had quite as unfavorable conditions and recovered. We cannot refrain from commenting on an article in the MEDICAL RECORD of October 6, written by Dr. J. J. Brownson of Dubuque, Iowa, under the heading, "Appendicitis—To Operate or Not to Operate." In the first paragraph Dr. Brownson makes the remarkable statement: "There have been more deaths from appendicitis since the operative method has been in vogue than during the expectant plan, which I believe is due to interference being practised at the wrong time." Our literature is replete with facts which directly controvert this statement. In Kelly's Monograph we note (p. 22) "Dr. Lewis (in the late fifties) wrote under the caption, 'A statistical contribution to our knowledge of abscess and other diseases consequent upon the lodgment of foreign bodies in the vermiform appendix, with a table of forty cases.' He declares that the obscure nature of this disease, its rapid and almost necessarily fatal termination invest it with a peculiar interest to the physician." The same author is quoted on page 23: "The prognosis is extremely unfavorable, as only three out of forty-seven recorded cases recovered." W. T. Bull, in the MEDICAL RECORD in 1873, analyzes sixty-seven cases; thirty-two recovered, thirty-five died. Kelly (p. 37) states: "It is of interest to note here the reduction of mortality from 'perityphlitis' after the introduction of the Parker operation. In 1867 the death rate was 47 per cent., while in 1882, when Noyes wrote, Parker's operation had been in use for fifteen years, and the mortality was reduced as low as 15 per cent." That the appendix is the source of practically all cases of peritonitis limited to the cecal region, and is the chief cause of generalized peritonitis, is now universally recognized. Nor can we doubt that our forefathers in medicine were dealing in a great majority of cases with appendicitis when they sent their patients to the grave with "inflammation of the bowels" and "idiopathic peritonitis." Appendicitis in times gone by has been a veritable slaughter of the innocents. Dr. Brownson states that as a result of following his theory that no operations should be performed during the so-called intermediate period there have been but two deaths in Dubuque county following operation for appendicitis since January, 1904. We think it is pertinent to ask Dr. Brownson how many have died of appendicitis in that time without operation. It is an easy matter to have a low percentage mortality if only selected cases are operated upon and desperate cases are denied the chance to live that an operation would give, for fear it would "injure the reputation of both the operator and the science of surgery." In the majority of cases of acute appendicitis in Appleton and immediate vicinity an operation is performed as soon as the diagnosis is made; but there are more deaths in the minority treated by the "do-nothing," "watch-and-wait" plan than in the majority under radical treatment. Dr. Brownson states also that "no case of acute septic peritonitis caused by the direct perforation of the peritoneal cavity will be found with a temperature of 102° and a pulse of 120; rather will they have a temperature of 105° or 106° and pulse of 140 or 160, together with a leaky skin, etc." We, too, have lived in the stage of surgical experience in which we made a god of pulse and temperature and worshiped at its shrine, with a simplicity born of childlike faith. But the rude awakening came as it will come to Dr. Brownson. Here are two cases in point which occurred in the practice of one of us.

A man entered the hospital with a history of having been injured by the toppling over of a pile of lumber. There were no visible signs of injury to the abdominal wall. Temperature normal, pulse under 90. During the following thirty hours moderate tympany developed and pulse and temperature increased, but both were less than 100. Peritonitis was suspected and the abdomen was opened. There was a diffuse inflammatory process as denoted by injection, effusion of lymph, and paresis, and there was no guesswork as the small intestine was "strung," as we say, from the duodenojejunal junction to the ileum, where a perforation was found. The patient died before the belly was closed. The second case was as follows: A patient was brought to the hospital on a stretcher with a history of having been kicked in the abdomen by a man four days previously. He presented the Hippocratic facies and tympany, but had a pulse of 92 and temperature of 101°. Laparotomy was performed. Profiting by the experience of the former case, a large incision was made and the intestines were turned out of the belly into towels wet in hot physiological salt solution to save time and avoid the trauma of running along the whole intestine in search of a perforation. There was a general peritonitis coming from a rup-

ture in the sigmoid. This was sutured and free drainage was established. The patient was sent to his bed with the remark that he did not have one chance in a million. He promptly proceeded to recover and left the hospital in six weeks a well man. If we had followed Dr. Brownson's theory that a temperature of 105° or 106° and a pulse of 140 or 160 are necessary to diagnose septic peritonitis from perforation, both patients would now be in their graves instead of one. Reference to the literature will show multiplied instances of similar sort. General peritonitis from perforated appendix is not unlike the same process from a traumatic rupture. All the patients die without operation. A few recover with operation, and we court the disrepute to "the operator and the science of surgery" engendered by saving these few. If Dr. Brownson is not convinced and still believes that cases of acute septic peritonitis from perforation are "forlorn tasks" with which a surgeon should not risk his reputation, let him attack Dr. John B. Murphy, who reports to the American Association of Obstetricians and Gynecologists thirty-six consecutive cases of general suppurative peritonitis from perforation with one death. For an account of the report see the MEDICAL RECORD of October 13, 1906.

We shall continue to operate in all cases of appendicitis at the earliest possible time, with the one exception above noted. But what do we mean by operating? We mean a surgical procedure done in the interests of the patient's life; and we do the least possible compatible with his interests. Relieve pressure and institute drainage—these are the keynotes. The exhibition of the perforated, gangrenous appendix is a minor consideration. As soon as the peritoneum is opened and pus is found, a large tube is inserted and retreat is made—even if there is an excess of peritoneal fluid turbid in character with a few flakes of fibrin on the presenting loops of intestine, further operation is immediately abandoned, and free drainage is established. These operations require but a few minutes and we believe in no case militate against the patient's chances of recovery. How can they? Has anyone ever doubted the ancient dictum, "Where there is pus evacuate"; is there anything sacred about a suppurating peritoneum; and is not this structure subject to the same laws of physiology and pathological physiology as are the pluræ, the liver, and the large joints? Whenever your patient has an acute suppurative infection of the peritoneum open the cavity instanter; but once it is opened, beware of pernicious activity.

810 COLLEGE AVENUE.

TREATMENT OF CANCER OF THE LARYNX BY SUBCUTANEOUS INJECTION OF PANCREATIC EXTRACT (TRYPSIN);*

A CASE OF GROWTH, SUPPOSED TO BE CARCINOMA, CURED.

BY CLARENCE C. RICE, M.D.,
NEW YORK.

I HAD the honor to present a paper of this title before the American Laryngological Association at its last meeting, May 31, 1906. I believe it will be of interest to direct the attention of this Society to the treatment of cancer by trypsin injections, because I have obtained a remarkable result in the case of a growth of the larynx, which furnished the basis of my former paper. At that time, May 31, the patient with a tumor covering almost the entire left vocal cord had gone to Europe in a half cured condition. When I last saw him the posterior fourth of the growth had sloughed away, the anterior three-fourths remained, but the ulceration had not healed at any point. I returned from Europe the middle of September. I was almost afraid to inquire about the condition of my patient, expecting that the ulcerative thickness had extended, and that perhaps a radical surgical operation had been demanded. But when I called to him over the telephone, at his place of business, he replied that his voice was much improved and that he felt perfectly well. He came to my office at once, and I found that the growth had entirely disappeared. The only conditions to be seen in the larynx which indicated that he had had any trouble at all was a mild congestion of the left vocal cord and a slight loss of tissue at the edge of the cord at one point.

It seems to me that you will agree with me that this is a remarkable cure. That the growth was removed by the effect of the trypsin injections, and by the pancreatic capsules called "holadin," there can be no doubt, because no other treatment was used. My associate, Dr. Ferguson, and I were positive that the growth which covered almost the entire length of the left vocal cord, and extended slightly up the side of the larynx, was malignant in character, because it had every appearance of malignancy. It was a dry, hard, grayish enlargement, having a nodulated, irregular surface. It was in appearance unlike any benignant growth I have ever seen. The only reason that we think it may not have been a malignant growth, is the fact that it disappeared entirely under the influence of this treatment.

The laryngologist, who is accustomed to examine tumors of the larynx, can pretty surely determine, without microscopical examination, the character of a growth. Malignant growths as a rule give the appearance of involving tissue more deeply than benign ones, and they have a firm, irregular surface that benignant ones do not. This growth had the irregular surface that is sometimes seen in papillomatous growths of the larynx, but papillomata have a friable breadcrumb appearance. They look as though the surface could be rubbed away with the finger. The benign fibroma is usually single and has a small attachment.

Dr. Frank Hollister, who referred this case to the office, had examined the larynx a number of times and told me that he was positive that it was carcinoma of the larynx. It was a favorable case for surgical operation because the growth was localized and the glands were not involved.

At my suggestion, Dr. Hollister gave his consent to the treatment of the patient by pancreatic injections. It seems to us, that no matter what the character of the growth was, its absorption and disappearance by reason of the effect of the remedies used, is a remarkable occurrence and worthy of consideration. We did not remove a portion for microscopical examination, because we did not wish to produce the irritation which would have followed the use of any cutting instrument, and I believe it is wise in the treatment of these cases to avoid all irritation by forceps or snare. Our attention was especially called to the desirability of avoiding such irritation by the conduct of another case of growth of the vocal cord which Dr. Ferguson was treating at this time. The patient, a middle aged, healthy man, had what seemed to be a simple fibroma of the vocal cord about the size of a small pea. This was at first removed by the snap guillotine. It showed a

*Presented to the Society of the Alumni of the City Hospital, November 14, 1906.

marked tendency to rapid recurrence. The uneven surface at the edge of the cord was afterwards reduced by forceps, but in a few weeks the growth had enlarged so as to cover one-half of the vocal cord. At this time the pancreatic injections and holaden were administered daily to this patient, in about the same doses as were used in our successful case, but no favorable results were obtained, and later the whole of the larynx was removed. We felt that it was possible that if the growth had not been subjected to any operative procedures, it too might have yielded to the effects of the hypodermic trypsin treatment. This latter growth did not present at all the appearance of malignancy which was present in the case which was cured. I give this as my explanation for not examining the growth microscopically:

Before giving in detail the history of the case which I wish to present to you this evening, it will be well to call your attention very briefly to the views of Professor John Beard, who occupies the position of Lecturer in comparative embryology in the University of Edinburgh, and who was the first, I believe, to use the trypsin injections in the treatment of malignant growths. In my first paper I premised the report of my case with a brief sketch of Beard's embryological work—his views as to the causation of cancer, and its evolution from the embryological viewpoint. This was in the main prepared from his own announcement of his ideas in an abstract of a lecture on Cancer, delivered before the Anatomical Society, the members of the Medical Institution, and of the Biological Society of Liverpool, January 20, 1905, and entitled "Germ-Cells in Relation to Malignant Disease." In this announcement Beard states what he believes to be the nature of cancer, based upon his own researches, pursued for many years, as to the origin of the germ-cells. All this had led him to conclude that "cancer has ceased to be a problem for the embryologist."

I also referred briefly to his published and now well known experiments—the trypsin injection of mice, inoculated with the "Jensen-tumor" which resulted, as he believes, in the destruction and disappearance of the cancer, under conditions which led him to state so positively the belief that his solution of the embryological problem of cancer had also led to the development of a cure for cancer.

Perhaps this is not an opportune time to review at length the theories of Beard. There is ample literature accessible and his views have been published to the world. It, however, might be said that Beard denies the parasitic origin of cancer and insists that one advocate of this theory refutes another. He asserts his belief that "the nature of cancer as an irresponsible asexual generation or trophoblast, has been known for two and a half years." In the description of his own work upon the origin of "the germ-cells" he states that his researches have established beyond question that "these are preembryonic in origin, arising upon an asexual foundation or trophoblast, and that by the self-sacrifice of one an embryo is unfolded to contain and to nourish the other germ-cells for a certain brief span of time." In every case examined it has been found that a varying percentage of the germ-cells failed to reach the right place in the body, and these may be found in almost any organ or position. "At first sight it had seemed that any one of these might later on give rise to a tumor, benign or malignant, for they represent, and in fact are, the hypothetical 'lost germs' of the pathologists."

Beard believes that "prior to the appearance of an embryo or sexual form, there arises an asexual foundation, the trophoblast, upon which the germ-cells and the embryo come into being. In a normal case, at a certain definite period the embryo is able to suppress the asexual foundation and the latter slowly degenerates. If, however, the embryo is absent, or very abnormal, the trophoblast may and often does become a very malignant form of cancer. The two generations have different nutritions, a fact of extreme importance, and the 'digestion' of a cancer exactly resembles that of the trophoblast of normal development. The mammalian embryo solved the problem of cancer ages ago. The very existence of the embryo is conditioned by the suppression, the degeneration, and death of the asexual generation, upon which it has come into being."

Speaking again of the "critical period," when the change in nutrition invariably occurs, Beard states that "the true problem of cancer is simply that of the antithesis of two digestions, that is, of two enzymes or ferments." He further states that "at the critical period the embryo, complete in all its parts, begins to nourish itself by an alkaline pancreatic digestion and with a ferment known as trypsin. If this latter is wanting, the asexual generation, the trophoblast, may become a malignant tumor of the deadliest description; if present, it becomes harmless, and slowly degenerates. Clearly, then, since cancer is an irresponsible trophoblast, the ferment which brought about its degeneration in normal development, ought to possess potency when directed against the cells of a malignant tumor. It is important also to note that just as cancer may be found anywhere in the vertebrata and just as there is one mode, and one only of development for all the higher animals, so also the pancreas and its secretion are a common heritage of the higher animals. The whole story of cancer is but another example of that antithetic alternation which underlies all the phenomena of living things."

Whatever may be the outcome of what Beard calls the "medical aspect" of his theory as to the causation of cancer, his long continued researches as an embryologist, at least entitle his views to respect, and they are to be corroborated or disproved only by the work of specialists in this same department of science.

As a result of Beard's experiments upon two "Jensen" mice by the trypsin injection, he states that it appeared to him certain that "the action of trypsin upon the cancer-cell is to pull down albumin (a living substance) and that its action is direct and ruinous upon the trophoblast or asexual generation." He expressed very remarkable confidence both as to the results of these experiments and their significance. He further states that the destructive action of the cancerous cells is due to malignin, a fact which was discovered by Petry in 1899. Beard further states that Prof. Jensen, whose brilliant work has been thoroughly recognized in Great Britain, did not succeed though he tried many times to transfer cancerous material from man to the lower animals. He did, however, many times transfer cancer from one animal to another of the same allied species, and so produced the so-called "Jensen mouse tumor." This was first done four years ago. I am not familiar with all of Prof. Beard's writings, but Saleeby says that Prof. Beard has, by trypsin injections, cured two mice and several individuals of cancerous growths. The theory is that trypsin acts upon cancer by digesting the cells and then the other pancreatic enzymes dispose of these products of digestion.

As for the medical aspect of this subject, it suffices to say that the matter came to my attention, as it has to that of many practitioners, in a way and under circumstances which led me to give it consideration. I do not propose to discuss Beard's theories or express any criticism as to his experiments or their significance; it is sufficient to say that this treatment has come to our notice at a time when the whole subject of cancer is receiving the most acute attention. The practitioner of medicine, familiar as he is with the present status of the subject, must maintain an expectant attitude toward any therapeutic measures directed toward the mitigation or cure of cancer. This treatment of Beard's, which is by the hypodermic injection of pancreatic extract, trypsin, certainly causes constitutional reactions which are worthy of serious study. The hypodermic injection of organic extracts is not new. We know that, generally speaking, when properly prepared and sterile, they are nontoxic; but they must be prepared by the trained specialist and under scientific laboratory methods. The suggestion of the hypodermic use of a potent digestive secretion of the pancreas gland with its enzymes was met with a feeling of hesitancy because of the possible effect of the trypsin, in view of its well known powerful proteolytic action, notably on fibrin and albumins. I was assured, however, by Mr. Fairchild, that the results of both experimental and clinical work had already established the fact that trypsin itself exercises no digestive or destructive action upon the blood owing to the presence of an antitrypsin body. Furthermore, that the "injection" was obtained from the fresh gland under rigid aseptic methods; was a 60 per cent. glycerin extract, sterilized by filtration under pressure through a Berkefeld filter, and taken up in vacuum into glass ampoules and then immediately sealed. The injection I have used was supplied by Fairchild, under these circumstances.

The hypodermic solution which I used, "injectio trypsini," contains the trypsin enzyme in its natural association with the other gland constituents, notably the amylopsin. To this fact special importance is attached by Dr. Beard, and after some months of observation he has expressed very strongly his conviction that certain symptoms which follow the use of the injections are not due to any direct action of the trypsin or to that of any of the pancreatic enzymes, but rather to the result of the absorption of the products formed by the action of the trypsin upon the cancer-cell, and to the dispersion of these throughout the system. And he suggests the use of an amylopsin injection in conjunction with that of the trypsin.

It is of significance in this connection, that the toxic effects produced by the *x*-rays are likewise said to have been due to the occasional disappearance of the tumors under the influence of the rays, and to the absorption into the system of the broken-down tissue products.

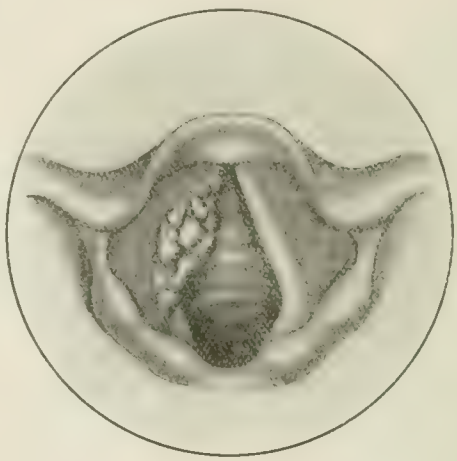
In accounting for certain symptoms which followed the use of the trypsin injections, we were strongly inclined to the view that they were due to the effect upon the system caused by the absorption of the tumor substance when it was attacked and disorganized by the "trypsin" injections. It should be remembered that this treatment has been employed for some months by numbers of practitioners in various parts of the world, and with results which in the main have been so far from negative that it is now, I learn, to be submitted to a thorough clinical trial by specialists, and at hospitals upon such a scale and by such a method as to conclusively prove its therapeutic properties.

I will now give the history of my case as it was presented to the American Laryngological Association. It is as follows:

George M., age seventy; father died of acute bowel trouble at the age of sixty; mother died of cancer of the breast at age of seventy-five. She had been operated upon two or three years before. There were twelve children in the family; nine died of consumption, ages twenty-seven to fifty. One was supposed to have died of cancer of the kidney, aged seventy-five.

Mr. M. had erysipelas forty years ago, which left a scar under the left eye. Six years ago he was sick in Paris for four weeks with an acute indigestion. He had had no other illness. Never had been a hard drinker or smoker.

The history of the present ailment is as follows: In December, 1905, he began to get hoarse. There was no pain about the throat or cough. He was treated by his family physician. We first saw him March 7, 1906. We found that his left vocal cord was covered or involved throughout three-fourths of its length anteriorly with a dry, hard, grayish enlargement, having a nodulated irregular surface, presenting a typical carcinomatous appearance.



The surface was dry and apparently not ulcerated. The injections were commenced at once, and repeated every second day. Five minims diluted with equal parts of water were injected under the skin of the abdomen each day for the first ten days. After that the dose was increased to 7½ minims every other day, which was employed for one week; later 10 minims every other day. Later seven and one-half minims every day and finally ten minims every day were used.

With these injections, holadin, which also is an extract of the pancreatic gland, was administered in three-grain capsules, one three times each day. The first effect of the trypsin injection that we noticed was a congestion and softening of the laryngeal growth. From gray it became red, from hard it became soft, and from dry it became moist. The posterior fourth of the growth sloughed away in small pieces, and had disappeared after two weeks' treatment. The surface of the vocal band from which the slough had disappeared was congested but smooth, and there was no appearance of regrowth. The remainder of the growth was at all times soft, and moist, and two or three pieces sloughed away, but when the patient went to Europe in the middle of May three-fourths of the length of the growth was still present. In elevation it had somewhat shrunken.

About a week before the treatment was stopped the hoarseness was suddenly increased, and we found that it was due to a marked congestion of the other vocal cord. Whether this was caused by an acute cold or by the effects of the medicines we could not tell.

We employed no other treatment. No doubt exists in our minds that the trypsin injections produced a very prompt and marked effect upon the growth. When the injections were given in the largest quantity, viz., ten minims every day, constitutional symptoms were produced. The patient complained of feeling generally ill, headache, slight nausea, pain through body, slight rise of temperature, never above 100. At such times the injections were omitted for one or two days, and all disagreeable symptoms disappeared. I should have said that the patient is in fine general health, quite as good as the average man of sixty. We felt that we could always trace a direct relation between the size of the dose of trypsin and the degree of the congestion of the growth.

One other symptom was noted, that is, a tendency to congestion about the lips, soft palate, and uvula. The congestion was followed by ecchymotic spots at these locations. We believe that they were undoubtedly caused by the trypsin injections.

We were very much encouraged for the first two or three weeks of the treatment, because, as we have said, one-quarter of the growth disappeared. During the latter part of the treatment there was but little improvement and the patient was so anxious to go to Europe that we finally consented.

The growth is entirely confined to the vocal band and shows no tendency to attack the sides of the larynx above. We only allowed him to use a cleansing spray. He is to be away for two months, and we hope to resume the treatment on his return.

This case seemed especially favorable for the trial of the pancreatic treatment because the growth is so localized; it had not been irritated by any form of local treatment, and the patient's general health is good. We have regretted that the patient's business has required him to talk a great deal. We feel that it could not have been merely a coincidence that the laryngeal growth commenced to soften and disintegrate in ten days or two weeks after the trypsin injections were commenced.

It will be noted that the patient has a marked inheritance in the way of cancerous growths. When the patient went to Europe in a half-cured condition, we gave him 100 of the holadin capsules, and he took these, three a day, until they were all completed. This was the only treatment that he received, except that he was given an ordinary cleansing spray. When he first came to us, his voice was very rough and hoarse, and it almost entirely ceased after three or four minutes' conversation. Since his return he tells me that his voice slowly improved during his ocean trip to Europe, but that it became much worse the first few days he was in Paris. He remained in Paris a week and traveled slowly during the following two months. During this time his voice gradually recovered and at present it is low pitched and somewhat roughened in quality; but he is able to transact his business without special vocal fatigue.

In the *Journal of the American Medical Association*, August 11, 1905, Prof. Beard in a short article on trypsin and amylopsin in malignant growths says that "this particular treatment has been in use for about six months and naturally it is still in the experimental phase of its existence." Further on Beard briefly outlines this method of treatment: "After a few preliminary injections of small amounts, that is, one-half ampoule of the injectio trypsini, the course should be: 1st—Injectio trypsini daily up to two ampoules for three or four weeks. 2nd—Then one ampoule of injectio trypsini on a certain day, followed by an ampoule of injectio amylopsini on the next day, and so on alternately for about four weeks. 3rd—Lastly, one or even two ampoules of the new injectio amylopsini daily for about four weeks, or longer, in the judgment of the physician.

"The injectio amylopsini, therefore, is meant to replace the injectio trypsini in the later periods of the treatment, and also even from the start to meet any bad symptoms, such as nausea, vomiting, pain in the back, drowsiness, albuminuria, high arterial tension, edema, etc. If any injections be still not well borne, the injections should be further diluted and given more frequently, but so that the total daily amount is not thereby diminished. It is easy enough to kill every cell of a cancer with injections of trypsin, but for its removal, and to prevent formation of poisonous products from its degeneration, injections of the diastatic ferment of the pancreas gland, amylopsin, are absolutely necessary." Beard thinks that the injections should be made into sound tissue as close to the growth as possible.

We consider it eminently proper to present these notes on the treatment of the case of supposed carcinoma of the left vocal band by pancreatic injection, the so-called trypsin treatment of Beard, for the reason that the results obtained left no ground for doubt that this treatment exerted a very prompt action upon the growth and was accompanied by certain well-marked local and constitutional symptoms. I am informed that there is a grave question as to the quality of the preparations which have been frequently employed in this treatment in London. We can readily believe that the slightest chemical change in, or the smallest degree of decomposition of the pancreatic extract would render them inert or inefficient and harmful. In this connection I can but express, as I know Dr. Beard has done, our debt to Mr. Fairchild as a specialist in the chemistry of the digestive ferments.

No fixed rule as to the exact method of treatment has been formulated. The quantity of injection which I employed, from seven to ten minims every day, is much less than that employed by Dr. Beard and others.

We have at the office treated four cases in all. Our successful case was the first one. Our second patient was a woman of sixty or more who was very near death when we first saw her. She had a cancerous growth involving the posterior wall of the larynx and the esophagus. She had been unable to swallow food for many weeks. It was a hopeless case from any standpoint, and although we gave the injections of trypsin no benefit resulted. The third case was the one already referred to, in which the growth, which seemed to be a simple fibroma, was removed by snare and forceps. After such removal the trypsin injections were used without benefit. The growth recurred and the entire larynx was removed. The fourth case we are treating now. This is probably an epitheliomatous growth attached to the lower pharynx on the right side which pushes the larynx and the epiglottis to the left. We thought for a time that we were getting marked benefit from the trypsin injections in this case, as the growth seemed smaller and softer and the swallowing was easier, but for the last two weeks there

seems to be no improvement. We are giving him a full ampoule every day. He is a poor man and has to come some distance to our office every day. He ought to be under better conditions in the way of eating and home living in order to give the treatment the best possible chance.

There may be one particular form of growth, and only one, which can be cured by the injections of trypsin, and it may be that the growth which we have seen removed is the particular type which can be controlled by pancreatic injections. What the exact quality of such a growth is, I do not know. All of these points must be ascertained by further study.

It is just as remarkable that the injection of trypsin will disintegrate one form of growth as another. In conclusion common sense would teach us that the earlier a case of cancerous growth is put under the trypsin treatment, the greater the chance of success. We feel, with Professor Beard, that the doses should quickly be made as large as the patient can judiciously bear. The unsatisfactory cases, so far as I have observed, have been those which have come under treatment in very advanced stages of the disease, consequently when the general health of the patient was very much undermined. We certainly are not giving the trypsin treatment of cancer a fair trial, unless we are conserving the general health of the patient by the best of care in the way of food, sanitary surroundings, and healthful living.

123 East Nineteenth Street.

TREATMENT OF PROSTATIC ENLARGEMENT.*

By JAMES PEDERSEN, M.D.,

NEW YORK.

MEMBER OF THE NEW YORK ACADEMY OF MEDICINE; AMERICAN MEDICAL ASSOCIATION; NEW YORK STATE MEDICAL SOCIETY; AMERICAN ASSOCIATION OF GENITOURINARY SURGEONS, ETC.

My purpose in this paper is to discuss the subject broadly, to indicate, if possible, what leads up to prostatectomy and what away from it, to cite cases in illustration and avoid the technical details of the operation in its several modifications. These details have been discussed sufficiently, sometimes to the exclusion of the more important considerations. The subject should be the patient, not prostatectomy; our object should be to net him the best results, not alone to perform an operation seductive because of the skill required and radicalism implied. Perfection in technique does not justify an operation not indicated.

The first of the important considerations is: When shall surgical intervention be advised? The second, logically: Which is the operation of choice in the patient under treatment? As to the time for surgical intervention, three teachings are recognized: (1) Immediately upon the first retention; (2) as soon as catheter life has to be begun; (3) when catheter life fails. As to the operation of choice we have to consider, in the order of our preference, (1) perineal prostatectomy; (2) suprapubic prostatectomy; (3) prostatotomy by means of either a bistoury applied through a perineal incision or Bottini's galvanocautery incisor.

At the present stage of our knowledge it is not possible, in my opinion, to say categorically when surgical intervention should be advised. We need more detailed, descriptive, and searching statistics, especially as to end results, on both the conservative and the radical sides. The exclusive advocacy of one operation as the operation of choice, I beg to submit, is unwarranted and futile. The variations in the state, degree, and complications of the pathological condition to be relieved should preclude a fixedly preconceived operation of choice.

Recent statistics of significant value are contained in the comprehensive paper by Belfield in Vol. IV of "Progressive Medicine," December, 1905. Further condensed they would show that the English and French, the former especially, advise the suprapubic operation; that the Germans are almost evenly divided, the slight though important preponderance being, however, on the same side; that with us the apparent choice is the perineal; that the mortality abroad and at home practically agree at about 9 per cent. as to the perineal operation and at about 5 per cent. as to the suprapubic, making about 7 per cent. for all cases. This differs from Watson's statistics based on an exhaustive analysis of 2,627 cases variously operated by 100 different operators (*Annals of Surgery, June,* 1904). He gives the mortality in 530 cases of perineal prostatectomy as 6.2 per cent.; in 243 cases of suprapubic prostatectomy as 11.3 per cent.; in 1,086 cases of Bottini's operation as 6.3 per cent., and in 207 cases of catheterism at 7.7 per cent.

I would agree with Belfield in commending Whiteside's paper (*American Journal of Urology,* July and August, 1905), in which a timely protest is entered against excessive enthusiasm for operating and a just criticism is made of the lack of ante-operation details. In a group of 238 mixed cases, Whiteside finds "absolutely good results in only 30 per cent.," a mortality in perineal prostatectomy of 20 per cent. in 36 cases reported by nine operators, of 8 per cent. in Murphy's 51 cases, of 5 per cent. in Young's 75 cases, and of 3 per cent. in Goodfellow's 75 cases. He pointedly remarks that the average of these mortality figures is not much better than the 13 per cent. given as the mortality twelve years ago, and he rehearses the "untoward results" found among the 36 cases already cited. While commending both his protest and his criticism, I cannot agree with his comparison. A just comparison cannot be drawn except from the statistics of a longer series of cases furnished with ante-operation details and "end-results" by several operators of more nearly equal skill. Supporting my point is the fact that Freyer's mortality of 10 per cent. in 110 suprapubic prostatectomies falls to 5.8 per cent. if his first 25 operations are thrown out and the results of the remaining 85 alone are computed.

I would next comment upon Albarran's report, the conclusions in which are drawn from his study of the end-results in his cases of perineal prostatectomy, 44 of which were inspected a year after operation and 15 after from three to four and one-half years had elapsed. All but 7 are regarded by him as complete successes in that they totally empty the bladder. Of these 7 failures (4 partial and 3 complete) he remarks as noteworthy, that 5 had small prostates and incomplete retention. The total number of *small* prostates he subjected to prostatectomy was eleven. Five of these had an enlarged median lobe; its removal was followed by a perfect result. Six had no enlarged median lobe and netted only one perfect result. He calls the pathological state presented by these six cases, chronic hypertrophic prostatitis. He says that it sometimes eventuates in complete retention; but that the partial retention is not due so much to visible obstruction as to imperfect opening of the urethrovesical orifice.

It is pertinent to remark here that these are the

*Read before the American Association of Genitourinary Surgeons at its twentieth annual meeting, June, 1906.

cases in which prostatotomy by either the Bottini instrument or a bistoury is of service when any surgical intervention is indicated, and that, as Albarran says, they are rarely benefited, in fact are often made worse by prostatectomy.

Case I., incipient prostatic enlargement, illustrates the value of palliative treatment in postponing indefinitely the necessity for radical measures.

V. R., 51, married, always a hard manual worker and looking older than his given age, had suffered frequency of urination, slight hesitancy and initial pain for two years. These symptoms had developed gradually; it was two months before they had reached their climax. The frequency rose to an hour and a half, and the complete emptying of the bladder meant a teasing desire gradually relieved by the discharge of a small quantity of urine every fifteen minutes. That the quality of his urine had had something to do with his symptoms is evidenced by two facts: the occurrence of a general pruritus apparently of lithemic origin concomitant with his greatest frequency, and the slight, temporary improvement that had followed medication by his physician. Recently the frequency had been two hours. He had had no venereal disease. His sexual life, which began with his marriage at 26 years of age, had been normal, barring a moderate frequency in coitus during the first five years. Desire began to wane with the onset of the bladder symptoms and he had not cohabited in the past six months. Examination showed three ounces of residual urine and an enlargement of the prostate, the left lobe especially, as felt by rectum.

Under treatment that comprised irrigations with and instillations of silver nitrate solutions, and digital massage of the prostate, his frequency at once began to decrease and his residual urine to diminish. This improvement has been constant and progressive. Since the eighth week he has been able to hold his urine three hours comfortably and up to four hours when necessary; he has not had to urinate more than once a night—many nights not at all—and the residual, accurately measured, is two drachms. His urine has been and is of normal appearance; the urethral length is 8½ inches; the prostate is now about normal in size, but dense and hard, the left lobe especially. He declares he is comfortable and that his urination is steadily improving. It is probable that if he could modify his diet and improve his assimilation, a further reduction in his diurnal frequency would result.

Case II. illustrates a class, many of which, undoubtedly, have been hurried into an unwarranted operation. It raises the question whether it is good practice always to perform prostatectomy on the occurrence of the first retention. The case is typical and not rare.

V. Q. J., 63, single, had been in the habit of holding his urine for an hour or more overtime during the preceding two years. Apparently, however, he experienced no urinary symptoms until a recent vacation that exposed him to unexpected discomforts and coarse, poorly-cooked fare. Within a few days there developed frequency, some ardor, considerable tenesmus, and incontinence whenever recumbent, awake or asleep. The frequency was fifteen minutes day and night. The incontinence amounted to a few drops when he was awake; but to a large volume when asleep. Under medical treatment by his physician the symptoms persisted for a week, then began to abate gradually. When he was referred to me, seventeen days after the onset, the diurnal frequency was only an hour and a half, only slight ardor remained, and the tenesmus practically had ceased; but the nocturnal frequency had been entirely superseded by the incontinence, made worse by the large quantities of water he was drinking by advice.

He has always been a total abstainer from alcohol; he has not used tobacco in twelve years; he drinks coffee twice daily. There is a history of a venereal lesion fifteen years ago without sequelæ. His sexual life has been extremely negative.

Examination showed an overdistended bladder reaching to the umbilicus and obscuring the contour of the prostate by bulging downward toward the rectum. Out of respect for the patient's exhausted condition and timidity, instrumentation was not undertaken on this occasion, his first visit; but the daily allowance of water was reduced to physiological limits, his coffee was restricted, and his fluid diet was replaced by solids. He refused to remain in bed until it should become imperative, though the possibilities were told him.

Within forty-eight hours the ardor and incontinence had begun to lessen, and when he reported to me at the end of that interval he was able almost completely to control the diminishing overflow. He had urinated only three times during the night. Gradual relief of the overdistended bladder was now begun. That night he rose but twice and had no incontinence. It never recurred. The next morning, at my office, after he had voided four ounces as usual, four and a half ounces were drawn, emptying the bladder, thus establishing four and a half ounces as the initial residual. That night he urinated but once. Three nights later he began to sleep through without urinating, and at the end of a week, after he had been taught to urinate in "editions," the residual was found to be only two and a quarter ounces. Seven weeks later, when tested again, it was only one and a half ounces; his diurnal intervals were two hours long on occasions, but three hours long as a rule; there was no nocturnal urination and he had recovered his strength. Two weeks later when he reported, he could hold his urine four hours. This condition obtains to-day. The urethral length is 8¼ inches; the prostate, by rectum, is broad, flat, and moderately enlarged; the urine is sterile.

In other words, this patient had complete retention, overdistention, and incontinence, due to an acute congestion of his enlarged prostate, all of which disappeared under treatment, leaving him absolutely as well as before. Barring the first three weeks, he was not seriously incovenienced nor kept from business, and had the retention been recognized the moment the incontinence developed or earlier, this period of three weeks would have been significantly shortened. The very prompt return of power to his detrusor is noteworthy. This result gives me satisfaction, and, considering the patient's temperament, environment, and lack of vigor, I think the satisfaction justifiable. To have operated would, I believe, have exposed him to an unnecessary risk.

Case III. illustrates a phase of catheter life that leads to a change of advice.

V. L., 60, married, when referred to me three years ago, gave the following history. For the past seven years he had been passing a soft rubber catheter once daily and irrigating regularly. He had gone along very comfortably holding his urine as long as seven hours, suffering only off and on from attacks of prostatitis and exacerbations of his chronic cystitis. Ten days before his visit an unusually severe attack had developed with the usual symptoms—great frequency, some urgency, sharp tenesmus.

After a week he stopped passing his catheter on finding that the residual was only a very little instead of "the quart" he had been accustomed to draw. He had had urethritis thirty years before and syphilis "two or three times." His habits as to alcohol, tobacco, and coffee were good.

Examination showed a large man in fair general condition. He urinated a feeble, dribbling stream. A soft rubber catheter entered easily and found four ounces of residual urine. The prostate was large, full, boggy, and symmetrically ovoid, as felt by rectum; it presented considerable intravesical enlargement to the searcher. There was no calculus. The membranous urethra was narrowed to 25 F.

After five days of preparatory treatment, including gradual dilatation of the membranous urethra, cystoscopy became possible and was performed. It proved the absence of calculus and demonstrated a large median lobe with considerable enlargement of the left as compared with the right. He remained under observation and treatment eleven days longer, then disappeared, the attack and exacerbation having so far subsided as to make catheterism only twice daily sufficient. The dilatation of the membranous urethra had reached only 29 F. Prostatectomy was offered, but not urged; the man's average comfort more than outweighing the very infrequent and temporary discomforts.

He appeared a year ago complaining that all voluntary urination had ceased, necessitating catheterism four or five times every twenty-four hours, including once at night, and that for the past three months he had suffered from recurring attacks of epididymitis.

After five days of treatment under observation it was clear that catheter life in his own hands had come to an end. Perineal prostatectomy was performed, the intravesical outgrowth as estimated by searcher, cystoscope, and rectal touch not being so large as to demand the suprapubic operation, and a complicating calculus having been excluded.

The patient made an uneventful recovery aside from a slight febrile movement the first three days and a mild phlebitis later on in his long-standing varicose veins of the leg. The iodoform gauze packing was removed the first day; the tube at the end of forty-eight hours. He was up on the tenth day and left the hospital on the eighteenth. The perineal wound had closed permanently; but he suffered a slight incontinence whenever the bladder became full, on which occasions he voided from eight to nine ounces, leaving a proven residual of three ounces. There was no nocturnal urination. Six days later he passed a small, black, irregular calculus with yellowish incrustations—undoubtedly a prostatic calculus that had been forced from its follicle during the prostatectomy.

Under persistent after-treatment the chronic cystitis improved and the residual fell to one and a half ounces. It is now stationary at two ounces. The incontinence obliged him to wear a urinal for about two weeks and continued in varying but gradually decreasing degree, favorably affected by rest and massage of the prostate, unfavorably by exercise and any dilatation of the urethra beyond 20 F., until at the end of six months it ceased. A few drops escaping when his bladder is very full and he is fatigued is all that remains of it to-day. His urinary intervals have been normal since he left the hospital; very rarely has he had to urinate at night; his general condition and health are good; he has gained about 18 pounds. For a time his potency was as before the operation; but latterly it has shown a decline.

In view of the otherwise good result, it is to be regretted that the very last portions of the prostate were not removed. Had this been done he might have been permanently relieved of all residual urine and that, in all probability, without having increased or prolonged his temporary incontinence.

Case IV. brings out one of the indications for suprapubic prostatectomy and presents other interesting features.

I. E., 68, married, came under observation last June in a forlorn condition due to prolonged suffering and neglect. The salient points of his long history were, that, about three years ago (having been on catheter life), he had had galvanocautery prostatotomy performed through a perineal incision; that he had left the hospital unimproved, had visited many dispensaries without benefit, and that from time to time sudden attacks of retention had occurred which he had relieved by passing the soft rubber catheter he used regularly before the prostatotomy. His constant subjective symptoms were great frequency, some urgency, marked tenesmus, and exhaustion.

Very little study showed that the attacks of retention were mainly, if not wholly, due to spasm. Under test, the bladder capacity was about two ounces. The searcher promptly detected a calculus and suggested a second. When cystoscopy became possible it revealed a deep, median groove below the internal meatus; prominent lateral lobes bounding this groove; a phosphatic calculus lodged beyond the border of the right lobe and partly overhung by it, and a second calculus, apparently caught in a secondary groove above the level of the internal meatus.

Knowing that the true state of the prostate could not be determined until some time after the calculi had been removed, litholapaxy was undertaken. Much to my chagrin the calculi could not be dislodged; only their free portions could be seized and crushed. A suprapubic cystotomy was therefore subsequently performed. The actual enlargement of the prostate was much greater than suspected; it resembled a thick ring obliquely surrounding the internal meatus. The groove dividing the median lobe was not deep enough to completely drain the bladder. The remains of the calculi were removed, complete prostatectomy was performed, and drainage above and below established.

The patient's powers of resistance were so low that the suprapubic wound became badly infected as soon as the tubes had been removed, which was on the fourth day. The perineal tube therefore had to be reintroduced. It was not until eighteen days later that it became permissible to remove it permanently. Thus, unavoidably a perineal sinus resulted which persisted despite every attention on my part consistent with his daily work, leaking more or less continuously for four and a half months. He left the hospital on the thirty-fifth day with the suprapubic wound firmly healed. Incontinence, apparent as soon as the perineal tube had been removed, persists, obliging him to wear a urinal. As was the case with the leakage, the incontinence ceases when he lies down, sometimes when he sits down. There is no nocturnal urination. On rising in the morning he voids from six to eight ounces in a free, forcible stream. The urine is feebly acid; but contains an excess of mucus and a few flakes and small shreds.

Possibly the patient could have been classed among those who do better when a preliminary suprapubic cystotomy is performed to rest the bladder by drainage and allow the patient to recuperate

his vitality before undergoing the prostatectomy. He has, however, done well, all things considered. He has gained flesh and strength; he is now able to do a full day's work in the factory with fair comfort. Sexually, he is as negative as he was for some time before the operation.

Case V. illustrates the condition called "prostatism without enlargement," the treatment of which calls for considerable study.

F. K. M., 67, married, complained that for "several years" past he had had to urinate once during the night and for a year past had had diurnal frequency—from once every hour to once every three hours, depending upon the quantity of fluid ingested and upon the character of his immediate mental occupation. To these facts he voluntarily added that some form of urethral instrumentation, given him three times weekly for six months about a year before, when the diurnal frequency first developed, had been of no benefit; but that after three days of treatment in bed for a gastrointestinal disorder, the urination had returned almost to normal and had so remained for "several days." He had escaped the venereal diseases, though his sexual life began when he was seventeen years old. From the day of his marriage until he was 50 he had cohabited several times weekly, thereafter once weekly, and had practised withdrawal regularly until he was about 45. He was still vigorous sexually, and now cohabited normally with perfect satisfaction. He had been a total abstainer from alcohol and coffee for the past year and from tobacco for the past thirty years. Considering his partially sedentary life, he was overeating and was not drinking enough water between meals.

Examination showed a healthy, active man, vigorous alike in mind and body. His urine, voided in a good stream without the slightest abnormal sensation, showed uric acid and calcium oxalate crystals in abundance, thus confirming the suspicion that the quality of the urine might be a partial cause of his frequency. The residual urine amounted to one and a half ounces. The prostate, by rectum, was of the small, firm variety, indicating interstitial changes. It was slightly tender. The urethral length was 8 inches.

Under regulation of his diet and fluids, supplemented by local treatment, the residual soon fell to half an ounce and the urinary intervals lengthened to an average of two hours when at his desk, to somewhat longer when exercising, and to four hours when recreating. Coitus once weekly not only was allowed, but also advised, observation proving in his case that it added to his comfort by helping to relieve the prostatic congestion.

This patient has been under my observation nearly two years. During this period he has had three slight and two sharper exacerbations, the former marked by increased diurnal frequency, the latter by a nocturnal frequency as well, plus, on two occasions, the characteristic pains of prostatic hyperemia. Coincidently there was an increase in the residual urine; but it never reached the original ounce and a half. The average residual to-day is six drams. Retention has never even threatened. All five of the exacerbations followed definite errors in diet; two were accompanied by subacute rheumatism in certain joints; one was aggravated by an unsatisfactory coitus. Through all, the urine has kept its normal appearance. None of the exacerbations kept him from business. In the intervals the days have been few when he could not hold his urine five hours if necessity demanded, though more frequent urination was more comfortable. Though this degree of frequency is an interruption, it is not an interference in his case; therefore even so comparatively trifling an operation as dividing the prostatic bar with bistoury or the Bottini instrument in the hope of further improving his bladder function has not been advised. In my opinion he is as near normal as a man of 69 can expect to be, and by reasonable attention to his diet, habits, and mode of life, I believe he can always keep his "prostatism" under control.

Whereas Bottini's operation has failed of universal application, it nevertheless has a well-defined, though limited place in the surgery of the prostate. This should be more generally conceded than it is, as the end-results reported by competent observers are undeniable. Granting that surgical intervention is demanded in the given case, the indications for the Bottini operation are: Prostatic bars; Albarran's chronic hypertrophic prostatitis without median lobe enlargement of any extent (chronic contraction of the vesical neck); advanced carcinoma of the prostate (Willy Meyer); prostatic enlargement when positive contraindications to prostatectomy exist. The contraindications to prostatectomy are those of any major operation; but advanced kidney disease probably will become less of a contraindication than in other fields of surgery, in proportion as operators attend to the preparatory treatment for prostatectomy, and as the two-stage operation comes more into vogue in critical cases. Among the writers making special mention of these points is Albarran, who counts chronic overdistention of the bladder and systemic infection from the bladder contraindications to prostatectomy until those conditions shall have been first relieved by catheterism, irrigation, and, if necessary, by drainage. It is doubtful whether we can yet assure a patient that he will be both potent and virile after prostatectomy. More evidence is needed. The procreative power, therefore, when made an imperative requirement, will still be a contraindication to any radical treatment. Old age, taken alone, is no contraindication.

Taking the patients with the symptoms of prostatic enlargement as they have presented themselves to my observation, the foregoing cases being type-illustrations, it is my opinion that the teaching which advises surgical intervention as soon as catheter life fails, comes nearest to being correct. Even this cannot be accepted, however, without further definition and a clear understanding of its qualifications. Thus, catheter life may fail at once upon attempting to establish it, or not until it has progressed for years; the patient may be unwilling to enter upon it, and insist upon immediate radical measures; the patient's susceptibilities, his intelligence, and his dexterity are factors for or against trying catheter life. Who shall say that the intelligent, dexterous man, able to care for himself, or that the man of extreme sensibilities, able to have a trained attendant, will not live at least as long and as comfortably as to his bladder function as his less fortunate neighbor who had to submit to an early operation, which, though it has enabled him to urinate perhaps with comfort, has not necessarily freed him from all complications nor sequellæ? Attention may be called at this point to what is implied in Albarran's statement that perineal prostatectomy is preferred because of the lower mortality; but that suprapubic prostatectomy will become the operation of choice as soon as the technique shall have been perfected, its results being remarkable, because it is followed by "no permanent fistulæ, no cicatricial contractions about the neck, no injuries to the rectum, no loss of sexual power."

My paper is not a plea for catheter life as opposed

to prostatectomy, for bare conservatism as against bare radicalism. It is submitted as an argument for discriminate intervention as against indiscriminate operating; for finer distinctions in the field of indications, and for a rational application of all the known methods and means of treatment in such proportions as shall gain the maximum results for each individual patient suffering from the condition known by the generic term, prostatic enlargement.

20 East Forty-sixth Street

SOME MENTAL SYMPTOMS DUE TO DISEASE OF NASAL ACCESSORY SINUSES.*

By J. A. STUCKY, M.D.,

LEXINGTON, KY.

That acute or chronic disease of the nasal accessory sinuses frequently gives rise to serious forms of mental disturbance is very evident from the number of cases of melancholia and suicide which are reported as being due to grippe or influenza. A few cases noted in my own experience in which the mental symptom was sufficiently pronounced to deserve record, especially in chronic suppuration of the accessory sinuses, leads me to bring the subject before this society for discussion.

I shall report only one case in detail; in the others only the mental symptoms will be given with the pathological findings as result of operation. All of these cases gave every evidence of chronicity, having existed for a long time. All gave the prominent characteristic symptoms of suppuration and were submitted to the usual diagnostic tests. All were operated upon after the Killian method, of entering the frontal sinus, removing the floor of the sinus, or enlarging the infundibulum, as well as removing the middle turbinate and the anterior ethmoid cells, and as many of the posterior cells as could be found which gave evidence of being involved in the suppurative process. In two cases, in addition to invasion of the frontal and ethmoid, the sphenoid was involved; in eight other cases, the maxillary sinus was also involved in the suppurative process.

The case which I shall report presented unusual and interesting neurological symptoms, and was seen by Dr. G. P. Sprague in consultation. Dr. Sprague's notes are given in detail, followed by notes of my examination, as well as the operation which followed.

Case I. White, male, age 44, consulted me on account of pain over right eye. The left eye turned in; he had double vision when looking with both eyes; slight ptosis of left lid; pain over eye was worse at night and on arising in the morning and was aggravated by exercise or stooping over. Discharge of yellowish fluid from nose gave relief for several hours. The following are the notes of the examination taken by Dr. Sprague: "Patient examined August 3, 1906; he said that in November, 1904, having been in good health, he suddenly became deaf in the right ear, soon after which it seemed as though there was a lump the size of a man's fist in the right nasal region, in which all sounds accumulated, and became confused or lost. He had no other symptom until late in December, 1905, when he suddenly began to have a sharp pain—which has never since spontaneously ceased—over the entire right half of the brain; the worst pain being over the parietal protuberance. About six weeks after the pain began he suddenly began to see double and found that the left eye had an internal squint; both eyes have failed considerably, and the pain extends all over the right eyeball. With the beginning of the strabismus, the breath became vile, the tongue heavily coated, and there was a slimy taste, with lack of appreciation of the difference in the taste of foods. Upon examination, the skin of the entire right side of scalp and right side of face, exclusive of the external ear, and following a line near the insertion of the lower teeth to the middle line of the chin, is lacking in sensation, although not wholly anesthetic. The right pupil is enlarged and stellate; left pupil is smaller than right, and both react very slightly and slowly to both light and distance. Tongue is without tremor, but sharply deviates to the right. Knee jerks are normal; there is no ankle clonus. Shuffles in walking, and leans forward, with head extended. Right eyelid droops very little. Grip of both hands normal. Has no aphasia. His family physician says that his mind is more sluggish, that he is more religious than formerly, that he occasionally 'preaches' in a wild manner about himself, and that he talks differently than when well, and uses wrong words at times, unless he talks slowly. His digestion is good and his bowels regular."

My examination—ophthalmoscopic—is negative so far as fundus is concerned, except for slight swelling of edges of disk. Right pupil irregularly dilated; no evidence of iritis or synechia; media clear; vision 20/40 when looking with one eye, 20/50 when looking with both; lens do not improve vision. Hearing normal; no evidence of disease of drum head or middle ear. Examination right anterior nares shows a contracted and degenerated middle turbinate closely adhering to antral wall, completely occluding the middle meatus at its lower border; a thin yellowish discharge without odor oozes from upper part of middle meatus; when wiped off with cotton quickly returns on bending head downward. Left anterior nares normal. Post rhinoscopic examination showed right side blocked with bluish mass covered with yellow pus and mucus; left side was normal. Tenderness on percussion over right frontal sinus, more marked on deep pressure, especially under the orbital ridge and at the inner canthus.

Transillumination of the sinuses is negative, except the right frontal, which is decidedly positive. A diagnosis of disease of the frontal ethmoid and sphenoid sinus was made and an exploratory operation advised, which was consented to. Under local anesthesia, the right middle turbinate was separated from the antral wall and removed with scissors and snare; this was followed by flow of pus from ethmoid cells, which were found in a degenerating condition. The post nasal obstruction proved to be of tough tissue, resembling exteriorly a mulberry and was adherent to the anterior inferior wall of the sphenoidal sinus. This was with some difficulty removed with the cold wire snare and was larger than an average sized chestnut. After the removal of this mass, the sphenoid sinus could be easily entered with a probe, and found to be filled with soft granulations which were removed with the curette. This operation gave prompt and pronounced relief.

On the following day, August 5, the patient was etherized for the modified Killian operation. The posterior nares was tamponed to prevent blood from filling the pharynx, and an incision beginning below the median line of the base of the nose on the right side and extending to the supraorbital notch along the upper edge of the eyebrow and as deep

*Read at the thirty-second annual meeting of the Mississippi Valley Medical Association at Hot Springs, Ark., November 6-8, 1906.

as the frontal bone. The periosteum was carefully elevated and retracted and the sinus opened with chisel near the median line and above the orbital ridge, the opening was enlarged with rongeurs sufficiently to admit thorough inspection. The lining of the sinus was greatly thickened, was soft and edematous and of a dark blue color, and filled with dark serous fluid; the infundibulum was blocked by firm granulations. These were removed with curette; the ethmoid cells were probed and found to have undergone polypoid degeneration; the bony opening was extended down below the junction of the nasal bones, which gave free access to the anterior ethmoid cells. These were removed with curette. After removing all morbid material, the bone edge was beveled and the frontal sinus was lightly packed with selvage gauze extending down into the nose. The incision was closed with the exception of a small opening for drainage at the inferior angle. The packing was removed the second day, and the nose and sinus irrigated with warm saline and alphozone solution (1 to 2,000) twice daily. The stitches were removed the fourth day, and the entire wound closed by the ninth day. The patient was up and walking around the hospital on the fifth day after the operation. The pain did not cease completely after the operation, but was so much relieved that he expressed himself as feeling like a new man, and although he had acquired the morphine habit, having taken it twice daily for some weeks, was enabled to do without it after the first day. The nervous symptoms and religious boisterousness rapidly improved, and at this time are scarcely noticeable. His gait is steady, pupils normal; he does not see double though he says he is sensitive to bright light; there is little or no tendency to squint, but he still has a heavy feeling on the right side of his head. His conversation, facial expression and general condition is that of another man.

This case is one of the most unique in my series, and some of the symptoms I am unable to account for. There is no evidence of syphilis and his well-nourished condition does not suggest tubercular or intestinal trouble. He was on anti-syphilitic treatment for some months before being brought to me, and both the iodides and mercury pushed to the point of toleration, with only the result of increasing rather than diminishing the intensity of his symptoms.

In the series of cases which follow, only the prominent mental symptoms are given. Practically the same operation was done and the same results obtained, only the results were more marked and rapid. All were of the chronic suppurative variety.

Case II. Male, white, age sixty-nine. Disease of nose for thirty years. Last year or two intense and increasing mental depression, with fixed idea that his end is near and he will die suddenly. Operated June, 1904. Complete Killian operation on the frontal and ethmoid (both sides); offensive pus, granulations and necrotic bone removed. No syphilis or tuberculosis. Cured.

Case III. Male, white, age thirty-two. Disease of nose for five or six years. Last few months increased mental activity or excitability; insomnia and morbid suspicion of everything and everybody. Operated June, 1906. Right frontal, ethmoid and maxillary antrum contained pus and granulations; modified Killian operation and maxillary antrum opened through canine fossæ. Cured.

Case IV. Female, white, age twenty-one. Disease of nose for several years; for two weeks previous to operation, mind sluggish; indifferent to her condition or surroundings; responds slowly and hesitatingly to questions, but accurately. Operation March, 1905. Both frontal, ethmoid, and both maxillary antra full of offensive pus and granulations. Cured.

Case V. Male, white, age forty-two. Disease of nose for fourteen years; for some months troubled with insomnia and mental depression; feared he would take his life; had syphilis in youth. Operation January, 1905. Left frontal and ethmoid full of pus; no granulations. Cured.

Case VI. Male, white, age thirty-three. Syphilitic; disease of nose for four years; mentally depressed; indifferent to his whereabouts or surroundings; slovenly and immodest in his dress; whereas in his normal condition was a Chesterfield in his tastes. Operation June, 1904. Empyema of right frontal, ethmoid, and maxillary. Entirely relieved, but syphilitic deformity of nose rapidly followed operation.

Case VII. Female, white, age fifty-five. Great mental depression; desired to be left alone; this condition had existed for two months and growing worse; had so increased that she remained in bed for five weeks prior to consulting me, two weeks of which were spent in hospital under treatment for melancholia. Operation May, 1905. Frontal and ethmoid empyema. Cured.

Case VIII. Female, white, age forty-one. Disease of nose for seventeen years; morbid fear she would take her life; was in everybody's way; feared to be left alone. Operation August, 1904. Empyema right frontal, ethmoid, and maxillary. Entirely relieved except occasional migraine.

Case IX. Male, white, age thirty. Disease of nose for six or seven years; stupid from pain; sleeps a great deal; mind enough to do his work but felt sure he was losing his mind; would sometimes wander miles from home without a motive. Operation December, 1905. Empyema right frontal, ethmoid, and maxillary. Entirely cured ten weeks after operation but relief was immediate.

Case X. Male, white, age fifty-one. Disease of nose and throat for twenty years; had syphilis in youth; increasing mental depression with suicidal inclination (threats). Operation August, 1905. Empyema left frontal, ethmoid, and maxillary. Complete relief.

Case XI. Female, white, age thirty. Disease of the nose for eleven years; syphilitic; melancholia with suicidal inclination; asked to be locked up so she would not disgrace her family by killing herself. Operation May, 1905. Empyema left frontal, ethmoid, sphenoid, and maxillary. Complete relief.

The cause of the pronounced mental depression in the majority of my cases can better be explained by the neurologist and alienist, and we have as yet little data outside of the clinical history to base conclusions upon, owing to the fact that medical men do not attach more importance to the condition of the nasal cavities, either at the bedside or on the post-mortem table. When this is done, the association of disease of the accessory sinuses and cranial cavities will be more fully substantiated. "Whether the symptoms and conditions described are due to intracranial pressure, direct or indirect meningeal irritation, reflex nervous conditions, disturbed cerebral circulation, or toxemia, is not determined. But the fact remains that in these cases ventilation of the occluded sinuses or cure of the purulent process cured the psychosis; on the other hand, retention of pus aggravated the mental defect, or return of the purulent infection in the sinus was accompanied by return of psychosis." (W. Sohier Bryant).

The presence of pus or granulations in the sinuses is not necessary to produce marked toxic symptoms, with pain and mental depression. In some of my most aggravated cases, no pus was suspected and none found, but as soon as the obstructing middle turbinal was removed, the relief was immediate. "The etiology of this condition depends on the anatomic relation of the middle turbinates to the hiatus semilunaris and infundibulum. The air, in the frontal and anterior ethmoidal cells is imprisoned there by pressure of the middle turbinal against the lateral nasal wall, the turgescent tissues filling in the hiatus semilunaris and effectually blocking it. The lining membrane of the sinuses absorbs the oxygen in the imprisoned air and thus creates a vacuum. The absorption results in negative pressure and consequent swelling of the lining membrane with increased blood supply to this region. Stasis, to a greater or less degree, results; pressure of the congested tissues on the contained nerve endings, together with this stasis, produces the symptoms and results in reflex vasomotor disturbances in the circulation of the neighboring structures. This theory is advanced by Brawley, Robertson, Ewing, and Sluder, and seems to me to be worthy of acceptance.

The mental symptoms in the class of cases under consideration may be due to a meningitis of a passing type, namely a meningitis serosa (Amberg). The anatomical conditions favor the easy appearance of such a coaffection of the surrounding parts of the sphenoid, ethmoid, and frontal sinuses. Undoubtedly toxins developed by fermentation and putrefaction in the gastrointestinal tract—a faulty metabolism—and from the poison in the blood developing from acute affections (Stevenson).

These toxin-producing bacteria are probably the chief agents combined with the sepsis from pus absorption, the influence of which acts upon the cortical cells and nerve fibers of the brain. The proximity of the acessory sinuses to the brain is of signal importance if we can assume that an irritation of the brain, directly or indirectly, in predisposed or not predisposed cases, is caused by an affection which has its seat in the sinuses, the indications for interference is plain.

In conclusion it is worthy of note that in each case presented in this paper the ethmoid cells were extensively involved in the pathological process, and I do not now recall ever having seen a case of frontal or sphenoidal suppuration in which the ethmoid was not implicated. My observations almost force me to the conclusion that probably in the ethmoid or its "offshoot" the middle turbinate, is to be found the cause for the majority of cases of infection of the frontal, maxillary, and sphenoidal sinuses, and the statement made by me at this society in a paper on a similar subject in 1904, is repeated with greater emphasis at this time, viz., "the middle turbinal most frequently causes obstruction of the natural openings of the accessory sinuses and thus interferes with free drainage and ventilation, and the early removal of its anterior third decreases the necessity for more extensive and radical operations later."

Only the mental symptoms that were most conspicuous and gave rise to most anxiety are mentioned in this series of cases, but in these and in many other cases of chronic ethmoiditis I have noticed one or several of the group of symptoms associated with this disease mentioned by Beaman Douglas, the cause of which has not been explained. "It is evidenced by a slow deterioration of the mental faculties, an inferior quality of work, loss of memory, disability for continued application, overanxiety, general incapability, and procrastination."

In neurotic subjects and those with a lowered vitality from any cause, an ethmoidal, sphenoidal, or frontal sinus affection may start the vicious circle composed of the sinus affection proper and the neurasthenia or hysteric conditions which later we know, may reach a form and a degree which sometimes allows us to classify the bearer as one "bordering on insanity."

THE DIAGNOSTIC VALUE OF THE CYSTOSCOPE AND URETERAL CATHETER.*

By JOHN EGERTON CANNADAY, M.D.,

PAINT CREEK, W. VA.

SURGEON-IN-CHARGE SHELTERING ARMS HOSPITAL

Lesions of no part of the body are, perhaps, more difficult of diagnosis than those of bladder, ureter, or kidney. For many years surgeons felt the need of some means whereby they might obtain more definite information concerning the actual state of affairs present in a given pathological urinary tract. From comparatively simple and crude beginnings there have been gradually evolved through the united efforts of many colaborers diagnostic instruments of scientific precision and accuracy.

The entire subject is of comparatively recent date. In 1874 Tuchman collected urine from one ureter by compressing the mouth of the other with a forceps introduced into the bladder. About this time Hegar proposed tying the ureter per vaginam for the same purpose. In 1875 Simon catheterized the ureter by the aid of a finger used as a guide, passed through the dilated urethra. General anesthesia was required, the after-effects were unpleasant, and the procedure was difficult. Pawlik, a Privat Docent in the clinic of Billroth, discovered in 1880 a method of introducing the catheter by the guide of external anatomical landmarks; this method is not easy and yet has some practical points to commend it. In this method the operator is guided largely by the sense of touch. Newman, Kelly, and Byford have worked along the same lines without adding anything to Pawlik's method. Later Brenner, Grunfield, and Kelly began to practise ureteral catheterization by aid of endoscopy, which rendered the orifices of the ureters visible. Kelly, in his dry method, dilates the urethra gradually then introduces a speculum with an obturator which, on withdrawal, allows the bladder to fill with air. Then, by the light thrown from a head mirror, the ureteral orifices are located by direct vision. Morris exposed the mouths of the ureters by the use of straight tubes with obturators.

In 1876 Nitze conceived the idea of a cystoscope, after much patient effort, in which he was joined by Hill, Fenwick, Thompson, Boisseau, Du Rocher, Caspar, Albarran, and others, and by Leiter, an instrument maker of Vienna, the cystoscope has been so perfected that it leaves but little to be desired.

Inasmuch as for obvious reasons a comparatively limited number of physicians will ever make use of the cystoscope and ureteral catheter, and as not all cases can be catheterized, there will always be a demand for some other means of obtaining the separate urines of the two kid-

*Read before the West Virginia Medical Association, June 22, 1906, at Webster Springs, W. Va.

neys, Harris devised a segregator which acts on the principle of elevating the bladder wall by means of a bar passing into the vagina or rectum, as the case may be, so as to form a ridge or watershed between the orifices of the ureters, the urine being carried from the bladder by separate catheters. Luys invented an instrument consisting of two catheters, between whose tips is placed a curved metal part, which can be bent further if desired by a chain passing as the string to a bow on out to the handle. Over this curved piece of metal and chain is stretched a thin rubber cover. Guyon, in 1902, suggested a similar instrument, which was latterly perfected by Cathelin, one of his assistants. On the convex side of this instrument there is a spring covered by a thin rubber bag. This spring can be pushed out of a slit so as to form a septum which will fit accurately the posterior wall of almost any bladder. Fine catheters may be passed through the body of the instrument so as to come out on either side of the septum. This instrument is said to be fairly accurate and to cause no pain.

Neumann has a metal divider or separator which he places in the bladder that collects the two urines separately. Although the ureters usually open into the bladder three centimeters apart, many complications may arise to prevent accurate results. The ureters may not open into the bladder equidistant from the median line of the body. Urine may leak under the instrument. If the bladder should be at all sacculated this would be almost certain to happen.

Heusner has described a new urine separator based on the principle to which attention was called by Bier, that the flow of urine could be stopped by pressure on the ureter. The most effective point is the niche at the side of the fifth lumbar vertebra where the ureter passes over the hill formed by the iliacus muscle. The body is encircled by a sort of cylinder, and pressure is made over the ureter by a pad attached to a screw with a crank device; the center of each pad corresponds to a point two fingers' breadth above the umbilicus, their inner edge a finger's breadth from the median line. This device is said to control the flow perfectly. The uretercystoscope and catheter possess the advantages of almost absolute accuracy.

Quite a number of different cystoscopes are on the market; those of Nitze, Caspar, Albarran, and Brenner; Bierhoff, Young, Follen Cabot, and Tilden Brown have also made modifications of the original instrument. In the Brenner cystoscope the catheter emerges from the convex side, while in the instruments of Caspar, Albarran, and Nitze the catheter is situated on the upper or concave side. There are made operative, examining, photographic, and retrograde (for inspection of the prostate) cystoscopes. The instruments of Follen Cabot and Tilden Brown have attachments for irrigation of the bladder, while the apparatus with the catheters is *in situ*. This attachment, in cases in which the field of vision is continually being rendered opaque by blood or pus, is of great value. Some of these instruments give a direct view of a section of the bladder wall, while in others a part of the bladder mucosa is reflected on a prism, thence through the shaft of the instrument to the eye of the observer.

For the introduction and use of the cystoscope, local, and even general anesthesia will be necessary in some cases. The urine should be withdrawn and half an ounce of a 1 per cent. solution of cocaine or eucaine (which is less toxic and can be sterilized by boiling) is introduced into the bladder, a little of the same solution being left in the urethra as the catheter is withdrawn. To do successful cystoscopy the following conditions are a *sine qua non*: A urethra that will admit at least a 22 French sound, a bladder capable of containing from four to six ounces of clear fluid, or a solution that can be kept clear by the use of the irrigating cystoscope. A contracted bladder whose contents are continually being rendered opaque by an influx of blood or pus is a very unfavorable one for the use of the cystoscope; a week or more of preparatory treatment consisting of the administration of genitourinary antiseptics, bladder irrigation, and the passage of sounds. Not only will the urine be rendered aseptic, but the bladder and urethra will in some measure become habituated to instrumentation, and one will be enabled to judge of the amount of reaction that will be likely to follow the examination of bladder and ureters. The patient should be on a table, the buttocks projecting slightly over the edge, the thighs widely separated, the feet resting on chairs, or on a shelf provided for the purpose. If general anesthesia is used the patient should be placed in the lithotomy position; six to eight ounces of clear sterile solution usually produces sufficient dilatation for the purpose of a bladder examination.

With the obturator in place, the instrument is entered after the withdrawal of the obturator, the light is turned on, and the cystoscope is carefully held, so as to come in contact with no portion of the bladder mucosa or a burn resulting in ulceration may be produced. By raising or lowering the shaft of the instrument, revolving the beak from side to side, pushing forward or withdrawing the shaft of the instrument a little most of the bladder surface can be brought into view. By continuing these manipulations the orifice of a ureter can be brought into view and the catheter directed into it. To bring the left ureter into view, the ocular end of the cystoscope is swung to the right, and vice versa.

The beginner must naturally first make a study of the normal bladder. The mucosa has a normal yellow color. The surface vessels have an arborescent appearance. The surface of the bladder wall is distinctly but slightly trabeculated. When an air bubble has entered the bladder it presents a round, shining surface, from which the cystoscopic lamp is reflected. The protrusion of mucous membrane at times seen about the ureteral orifice may be mistaken for a tumor. When the bladder is not sufficiently injected the rugæ may be thought to be papillomata. The base of the bladder and the trigonum suggest a sandy shore in appearance. At the posterior angles of the trigonum are the mouths of the ureters, each appearing as a slit or depression placed in a little ridge of the mucous membrane.

The cystoscope is of undoubted value in the diagnosis of diverticuli, calculi, foreign bodies, *e.g.* a silk ligature in the process of extrusion from the bladder wall, simple ulcer, tuberculous ulcer, papilloma, malignant growths, polyps, fibromata, in fact all new growths. In cases of pyelitis, pus can often be seen escaping from the ureter. The appearance of the ureteral orifice is often characteristic in inflammatory conditions of

the renal pelvis. The extent and character of a cystitis can easily be determined.

Blood deposited on the normal bladder mucosa simulates a severe subacute or chronic cystitis. In the acute or chronically inflamed bladder the rugæ resemble papillomata, especially if the inflammation is localized. Some forms of chronic cystitis produce an even rectangular quilting of the bladder with projections between the seams of swollen mucous membrane. Acute and chronic cystitis causes the mucous membrane to vary in color from deep red to yellow, according to the stage and degree of the inflammation. Naturally, the correct interpretation of pigmentation, exfoliation, and color variation must be based on a thorough familiarity with the appearance of the normal bladder.

Tuberculous cystitis has some features that make its diagnosis at times difficult, and even impossible. The lesions are sometimes associated with growths of a papillomatous character. When sharply-defined ulcers develop in the absence of either acute or chronic cystitis, the diagnosis should be easy, though this condition in its early stages may be thought to be solitary simple ulcer. When thickening and infiltration is general and associated with the papillary growths mentioned above, diagnosis may be difficult. Bladder tubercle when about to break down shows itself in the shape of small, white caseous spots. In advanced tuberculous ulceration the bladder is apt to appear mottled, by reason of the alternating anemic and hyperemic areas. One ulcer may be ragged and red in outline or covered with blood clot; another may have on its surface a dirty gray slough and have undermined edges. In far-advanced bladder disease this organ becomes so irritable and contracted that the cystoscope cannot be used.

Simple ulcer usually presents a pale yellow slough, contrasting vividly with the red of the mucous membrane. Sessile growths and polyps are easily diagnosed by their appearance. Many papillomatous growths bleed easily and should not be touched during examination if possible to avoid it. Hemorrhage beneath the mucous membrane produces a yellow, projecting tumor resembling a papilloma. Malignant new growths of the bladder as a rule do not possess any very characteristic appearances.

The appearance of the orifices of the ureters is often corroborative or suggestive of certain renal or ureteral conditions, according to David Newman. When one orifice is altered and the other normal the kidney affected is on the side of the abnormal ureter. Congestion and swelling of the mucous membrane in the neighborhood of the orifice and along the ureter associated with pouting of the lips denotes acute irritation of the pelvis or parenchyma of the corresponding kidney. A dilated orifice, thickened lips with dark red mucous membrane between them, indicates descending ureteritis with dilatation. A punched-out orifice, thickened lips, induration, and congestion of the surrounding mucous membrane indicate a dilated ureter with ascending ureteritis. Simple dilatation of the mouth with local congestion suggests mechanical irritation of recent origin. A pinhead opening on a ridge of deeply pigmented mucous membrane denotes induration of the ureter walls from ureteritis. The vascular orifice denotes increased vascularity of the kidney. The golf-hole opening indicates atonic dilatation of the ureter. A calculus arrested near the mouth of the ureter produces edema of the orifice.

Much can be observed by a study of the shoots or the urinary afflux from the ureteral orifices. These shoots may be accentuated by giving methylene blue by the mouth or indigo carmine by hypodermic. When the urine shoots in distinct jets, but more frequently on one side than the other, greater functional activity is indicated when the shoots are large and uniform in size. If they are small in size, frequent or irregular irritation may be inferred. Stricture, stone, or inflammatory troubles are to be suspected when the shoots are irregular or distorted in form. The action of certain drugs, the drinking of fluids, excitement, etc., may cause a very rapid flow of urine. Dilatation of the ureter without paralysis of the sphincter is denoted when the urine dribbles into the bladder at intervals. When the sphincter has lost its efficiency the urine flows into the bladder almost continuously. When no urine is being secreted no shoots will be seen even after several examinations. The orifice of the ureter may be undiscoverable. The urinary shoots consist of blood-stained urine in acute inflammation of the parenchyma of the kidney, in breaking down carcinoma and sarcoma of the pelvis, in injuries of the kidney, in ulceration of the pelvis, in malignant disease, and in syphilis; occasionally slight bleeding is seen in stone, in early tuberculous disease, and in chronic interstitial nephritis.

The flow of urine from the ureter is pus stained; in septic pyelitis and pyonephrosis, when the kidney is still active, the urine will be ejected at regular intervals. In tuberculous pyelitis the pus is not intimately mixed with the urine and many of the shoots will be clear; most of the pus passed will be in the shape of flakes. In old-standing pyonephrosis, in advanced tuberculous, syphilitic, or malignant disease, the secretion of urine will have practically stopped and pus, blood, or bands of puttylike material may come from the ureters.

About the most easily discovered morbid object in the bladder is a stone lying on its floor; this stone may be covered with mucus or be in such a position that it cannot be reached with a sound. At times a calculus will float in the urine content of the bladder. The stone may be lying behind the prostate and may be brought into view by placing the patient in the knee-elbow position.

Ureteral catheters can best be sterilized by suspension in a rack in a container over formaldehyde solution. Just prior to its introduction into the bladder by way of the cystoscope the catheter should be lubricated with glycerin or oil. As a precaution against a possible introduction of infection into the ureter and renal pelvis, some irrigate through the catheter with a small amount of dilute silver-nitrate solution. In introducing the catheter one should be careful not to touch the bladder wall with its tip.

The ureteral catheter is of especial value in determining in a given case which of two kidneys is involved. Strictures of the ureter may be located, dilated, and treated, and some mild cases of hydronephrosis may be cured by this means. Stone in the pelvis of the kidney has been detected a number of times by the use of the wax-tipped

bougie. Inasmuch as the introduction of the ureteral catheter often causes some bleeding, it is well, especially in uncertain cases, to leave it *in situ* for some time. In addition to its value as a diagnostic instrument, the catheter is useful for the purpose of lavage of the renal pelvis and as a guide and protection to the ureters in certain cases of pelvic surgery.

The cystoscope and ureteral catheter should be, as a rule, used in cases in which a positive diagnosis cannot be made by other means. In the introduction of the instrument into the bladder, with the possible traumatisms incident thereto, a certain risk of infection is incurred. In the same way there are chances of ascending infection of the ureter and possible kidney involvement from the use of the ureteral catheter. A few cases of contracted bladder and certain cases in which the hematuria or pyuria is excessive cannot be satisfactorily cystoscoped. In cases of stricture so large an instrument cannot be passed. At times it is impossible to catheterize the ureters. Time, patience, expensive apparatus, excellent eyesight, extensive experience, and skill are prerequisites to the accomplishment of results from this sort of work. Some patients cannot tolerate this procedure even by aid of a local anesthetic.

In a considerable number of otherwise obscure cases I believe the cystoscope and ureteral catheter to be of much value, and that they fill a want in our armamentarium of diagnosis that nothing else will.

My conclusions are that the cystoscope as an accurate scientific instrument is of comparatively recent inception and perfection; that the other mechanical aids to the collection of the separate urines are not by any means absolutely dependable; that the cystoscope and ureteral catheter have their limitations, shortcomings, and defects, and are not ideal; that these appliances are of especial value in diagnosing the causes of hematuria, in the discovery of calculi and foreign bodies in the bladder; that a careful study of the ureteral orifices gives more than an inkling of the conditions present in ureter and kidney. Definite information concerning the origin of a pyuria can be elicited by the use of the cystoscope and ureteral catheter which could not have been obtained in any other way.

The Origin and Structure of Moles.—Dr. Wilfred S. Fox has made a study of moles, and in a subsequent paper will discuss their relation to malignancy. He considers that the tendency of research into the origin of cancer has been toward abandoning the infective hypothesis. Moles are of two general classes: smooth or abnormal pigmentations, and verrucose with hypertrophy. He makes the following groups: Vascular nevi, dermoid cysts, hard nevi, soft nevi, (or moles as generally understood), giant nevi, linear nevi, and mullusciform nevi. His paper deals chiefly with the commoner forms of hard and soft nevi. He finds that though congenital in their origin, moles are seldom actually present at birth, but develop during the first year or may be delayed till puberty. Von Recklinghausen's and Unna's views as to origin are discussed. The conclusions drawn from a series of cases examined and from the evidence given by histological workers are that the cells of soft moles which show the typical columnar formation in the corium are epidermal in origin, but that there does appear to exist a more rare variety of soft mole, which resembles clinically the above, but whose cells are in all probability derived from the mesoblast.—*British Journal of Dermatology.*

Recurrent Luxations of the Patella.—According to Dupic, in cases in which the first dislocation has been spontaneous or caused by trauma this accident may be brought about afterward by merely an energetic contraction of the quadriceps extensor femoris. This dislocation, which occurs more commonly than is generally thought, is found most often in young subjects from twelve to twenty years old. Two-thirds of the cases are girls and women. The dislocation occurs nearly always on the external side, and is of two principal varieties, being complete or incomplete, according to the degree of the displacement. As a predisposing cause there generally exists an affection which distends the ligaments, such as hydrarthrosis, a bony deformity, or a slight degree of genu valgum. In such conditions a violent muscular contraction, when the leg is half flexed, is sufficient to bring about the displacement. The prognosis of these dislocations is always serious and depends upon the number and location of the recurrences. The number of recurrences is extremely variable. In some cases they take place several times a day and even oftener. The degree of the dislocation is equally important. Sometimes it is so slight that the function of the part is hardly disturbed. In other cases the dislocation is complete, with absolute functional impotence. Reduction is generally easy. Immobilization should be enforced for about eight days, after which massage and electricity are indicated. However, when recurrent dislocation becomes chronic surgical intervention is indicated.—*Gazette Médicale de Strasbourg.*

Acute Intoxication by Mercury.—Barthe and Ch. Mongour record certain observations which they have made. There are three distinct phases in cases of this kind, the initial period being separated from the terminal by an absolute cessation of symptoms in certain instances. The first period begins soon after the ingestion of the poison. It is characterized by bilious vomiting, followed by hemorrhagic fluid. A painful sensation of burning in the retrosternal and epigastric regions is very troublesome. In the hours which follow, salivation develops, with lesions of mercurial stomatitis. There is also fetid diarrhea, the dejecta being bloody and stringy. This period lasts from two to five days. As to the condition of the blood, the leucocytes, according to their power of resistance, tolerate a mercurial infiltration for a period more or less long. When the lesions of the digestive tract begin to heal, this tolerance still exists and the patient appears to be entering upon convalescence. But the mercury later disorganizes the white cell, which then allows the poison to diffuse itself throughout the entire organism. The general symptoms of the third period then develop. Although the white cells do not play an exclusive rôle in the defense of the organism, they are the most important factor. This whole subject is of medicolegal interest.—*Journal de Médecine de Bordeaux.*

A Benign Tumor Developed on the Interior Surface of the Labium Minor.—Gaignerot reports this case. The size of the tumor corresponded to that of a mandarin. It was elastic, of unequal consistence, and had on its surface a series of nodosities of woody hardness and of the size of small peas. At the time of its extirpation its color was a pinkish yellow. On section this tumor was seen to consist entirely of small granules like those that covered its surface, hard and yellow. These granules were connected by a gristly tissue, slightly translucent. Microscopically this growth was found to be a fibroma, with lipomatous patches here and there. The tumor was interesting on account of its location. The patient was fifty-four years old and entered the hospital for the treatment of an umbilical hernia. It was by chance only that the tumor was mentioned. She had noticed a small swelling at the age of seventeen years. This growth had increased in size up to the present time.—*Journal de Médecine de Bordeaux.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 24, 1906.

THE ARMY MEDICAL DEPARTMENT.

THE report of the Surgeon-General of the Army for the year ending June 30, 1906, recently issued, shows a gratifying increase in the health of the troops and in the sanitary conditions in the various posts. The mean enlisted strength of the Army, excluding native troops in the island possessions, as reported in the monthly sick reports of the Medical Department, was 56,901, and on returns to the Military Secretary's office, 58,556, the difference representing those temporarily absent from a command. The total number of admissions to sick report was 73,742, an admission rate of 1,295.97. This rate was 1,354.89 for the previous year, and 1,903.31 for the sexennial period 1898 to 1903. As in many diseases, the same man may be admitted several times, the total number of admissions is, of course, greater than the actual number of cases. The death rate was 6.28 per thousand, compared with 6.75 for the previous year and 16 for the sexennial period 1898 to 1903. As usual, venereal diseases were the most important affecting the efficiency of the Army, and next to these came malaria. Then followed diarrheal diseases, but in these there was a most decided improvement, the admission and noneffective rates being 84.67 and 2.87 respectively, compared with 108.36 and 3.87 for the previous year. Alcoholism was next in order, and in this, thanks to the continued prohibition of the canteen, there was an increase in the admission, death, and noneffective rates compared with last year.

The average enlisted strength of the troops serving in the United States was 42,834. Among these the admission and death rates were 1,305.83 and 6.44 respectively; these were lower than for the previous year, but slightly higher than for 1903. Venereal diseases led the list as causes of admission, and following these in order were bronchitis, diarrhea, malaria, and influenza. A study of the causes of death shows that over 42 per cent. were due to external causes, and of these 23 per cent. were suicidal and 20 per cent. due to drowning. Among the causes of death from disease, tuberculosis led, with a rate of 0.86, as against 0.68 for 1904; pneumonia, typhoid fever, alcoholism, and appendicitis were next most potent as causes of death. There was a most remarkable and gratifying diminution in the number of admission for typhoid fever during the year, the total number having been 153 and the rate 3.57, as against 247 and 5.62 for 1904; the death ratio, however, was a little higher than for 1904, 0.30 and 0.27 respectively. There was an improvement in the ratios for malarial diseases.

General O'Reilly adds his testimony to that of the other officers of the Army regarding the havoc to health and morals wrought by the refusal of Congress to restore the canteen feature of the post exchanges. In discussing alcoholism, the admission rate for which increased from 25.42 in 1904 to 30.22 in 1905, he says: "Many medical officers consider that the abolition of the sale of beer in post exchanges has had much to do with the increase in alcoholism and venereal disease, by driving the soldiers to disreputable resorts outside of the post and beyond the control of the post authorities. In that opinion this office concurs." It is strange that the good ladies of the W. C. T. U. and other advocates of compulsory temperance, so called, cannot see that true temperance in the Army would be promoted by restoring the canteen privileges. If soldiers could spend their evenings in innocent games over a couple of glasses of beer at the post exchanges, all, except the most vicious and the confirmed dipsomaniacs, would be content, and sobriety, a very different thing from total abstinence, would be promoted. The men resent this motherly restraint, and improve their leave by spending it in the many dives which have sprung up immediately outside the posts since the canteen was abolished. There they drink spirits instead of beer, and, when inflamed with alcohol, consort with the vicious and diseased women attached to the dives. It is a pity the President has not the authority to order the restoration of the canteen feature of the post exchanges, as he apparently had to order the deformed spelling which disfigures this otherwise interesting report of the Surgeon-General. He would assuredly do so if he could.

The bill to increase the efficiency of the Medical Department of the Army, which was passed by the Senate in the former Congress, but failed to come to a vote in the House, was introduced in the present Congress, and passed the Senate in the spring of 1906. It was favorably reported by the Committee on Military Affairs in the House about the same time, but did not come to a vote in the first session. It is to be hoped that this vote will be reached early in the second session. "The need of an increase in the Medical Corps," General O'Reilly says, "is evidenced by the fact that there were on June 30, 1906, 166 civilian physicians employed under contract. The need of increasing the attractiveness of the service is shown by the fact that during the year no progress has been made in filling the nineteen vacancies now existing, the number of accepted candidates commissioned being exactly equaled by the losses occurring during the year. It is impossible for the Medical Department to reach a high degree of efficiency or to escape a lamentable breakdown on the occurrence of war if Congress does not come to its relief. Nor can this relief be postponed until war is imminent, for the selection and training of medical officers is a gradual process which requires years of time, and an efficient medical corps can no more be created out of hand than a tree can be made to grow in a night."

The strength of the Hospital Corps on June 30, 1906, was 3,196, a gain of 136 during the year. The number of female nurses was 97, employed at the Presidio, San Francisco, Fort Bayard, and vari-

ous posts in the Philippines. Some embarrassment in recruiting this corps has been caused by the greater inducements offered by the Isthmian Canal Commission, so that now there is the smallest eligible list from which appointments can be made to the Corps since its organization. Recommendations for similar provisions for Army nurses have been made, and as time goes on, the Surgeon-General says, the wisdom and necessity for such become increasingly evident.

In accordance with the recommendations made by the Surgeon-General last year, the Secretary of War, on October 21, ordered the establishment at the United States Military Academy, West Point, of a Department of Military Hygiene, with the senior medical officer at the academy as the head of the department and a member of the academic board. This is a great step forward, and will no doubt have a very decided effect in advancing the cause of sanitation in the Army. The line officer, having been instructed in the elements of hygiene, and as a result of this having been made to appreciate the value of sanitary measures in maintaining the effectiveness of the troops, will be less inclined to regard such measures as foolish and unnecessary, and to oppose obstacles to the efforts made by the medical officers to enforce them. Another recommendation made in the report of last year has been adopted, and a permanent board for the study of tropical diseases in the Philippines has been detailed, Assistant Surgeons Ashburn and Craig constituting this board.

Experiments have been made during the year with the so-called "galloping ambulance," a British invention, two of which have been purchased for the department. This vehicle is intended for rapid ambulance service with mounted troops, and the results obtained with it so far have been very satisfactory. A motor ambulance has also been under trial, and the Surgeon-General is convinced, as a result of this trial, that some type of that class of vehicle will form a necessary part of ambulance equipment for both post and field.

General O'Reilly renews his recommendations of last year in regard to the systematic physical training of all soldiers, and strongly urges that the proper steps be taken to carry into effect those recommendations. "Commencing with a gymnastic course to develop gradually the weak points in each soldier and give him agility, strength, and the control of his muscles, the course would go on through outdoor athletics to military gymnastics or gymnastics applied to overcoming the obstacles which the soldier is likely to meet with in warfare."

The report presents a number of other interesting facts regarding the Army Medical Museum, the library of the Surgeon-General's office, the Army Medical School, the work of the Medical Corps in the Philippines, the Army hospitals, etc., and bears witness to the great achievements of the Surgeon-General and his most efficient aids in the Medical Corps against the odds of the indifference of Congress and the unreasoning prejudice of some officers in other branches of the service. The medical profession of the country has very good reason to be more than satisfied with its representation in the United States Army.

INTESTINAL DISINFECTION.

In the treatment of many conditions in which an infection of the intestinal tract with pathogenic bacteria constitutes one of the features of the disease, the endeavor has been to bring about a more or less aseptic condition of this portion of the alimentary canal by the administration of certain drugs, astringent or antiseptic in character. Considerable doubt, however, has been expressed as to their value, particularly as to the degree of their disinfectant properties. If their action is germicidal, then, it has been suggested, this effect is also manifested against the normal bacterial flora of the intestine, which, as is well known, is essential to the proper conduct of the intestinal economy. In addition to this, it has been claimed that an unimpeded growth of these bacteria forms one of the most important means by which the pathogenic invaders are destroyed and eliminated. Intestinal antiseptics, therefore, apparently work in opposition to the natural defensive efforts of the organism, the development and preservation of which it should be our aim to encourage.

This subject was discussed at the recent Congress of German Naturalists and Physicians in Stuttgart, at which some interesting suggestions were brought forward in a paper by Moro (*Münchener medizinische Wochenschrift,* October 9, 1906). He held that the ideal way of combating intestinal infection would be by the introduction into the canal of the normal bacteria or by providing conditions in the intestine suitable to the further development of the harmless bacteria already present. The oral administration of bacterial cultures must be ruled out for various reasons, but in place of this the speaker suggested, in the presence of infectious process in the large intestine, the rectal injection of the proper organisms. Thus the colon bacillus, which is said to inhibit the growth of the organisms both of typhoid fever and of dysentery, might be given per enema in fluid agar cultures. A less radical method would provide for the maintenance of conditions favorable to the growth of the bacterial flora already present in the gut, and this end might be attained by appropriate feeding rather than by drugs. Moro found, for example, that *Bacillus bifidus,* a nonpathogenic organism present in the intestine, grows with surprising rapidity when human milk is administered and soon appropriates the field to itself, the other bacteria being repressed. The discovery in its present shape is not likely to have any immediate application, for it would hardly be feasible to supplant the trained nurse by a wet nurse in a case of typhoid fever in the adult, but it may be possible to discover the element in human milk which favors the growth of this organism and so to turn the discovery, if discovery it is, to practical account.

It would be worth while to follow up this lead for a time to see if it is really of value, for the successful control of intestinal infections still constitutes one of the leading problems of medicine. Intestinal antiseptics, although introduced in great variety, have not been generally successful, and this failure has led to the introduction of the serum treatment in certain forms of dysentery and in typhoid fever; but though encouraging results have

been obtained, the therapeutics of intestinal infections still lacks much before it can be placed on a firm and practical basis.

PROSTATECTOMY IN TWO STAGES.

Among surgical procedures in general there is none attended with more hazard, comparatively speaking, than the removal of the prostate gland under certain conditions. Although the percentage of mortality has been greatly reduced within recent years by improvements in the technique of the operation, there are factors which prove an almost unsurmountable barrier to a successful outcome. Among the most noteworthy are the age and generally reduced vitality of the patient added in most cases to an impaired condition of the kidneys and other internal organs. The kidneys bear such an important relation to the immediate recovery and future prognosis in every patient that any damage which they may have previously sustained will probably be seriously aggravated by the additional strain imposed by an operation of this character. Hemorrhage, shock, urinary suppression, and general toxemia may be summed up as the main difficulties consequent upon a prostatectomy, and the mortality rate will be found to bear a more or less definite relation to the existence of these features in any given case.

A complete and radical removal of the gland, particularly in cases in which an emergency exists, necessarily increases the hazard. In order to improve the patient's chances, C. H. Chetwood, writing in the *Annals of Surgery* for October, 1906, suggests that the operation under such circumstances be done in two stages. He reports a series of eight cases of a severe type and threatening in character, in which death would almost infallibly have followed a radical primary operation. The ages of the patients varied from sixty-five to eighty years, and all could be classified as poor surgical risks. After preliminary drainage a complete radical removal of the prostate was done in each case with excellent results, the former giving the patient immediate relief from his symptoms and an opportunity to gain in strength as a preliminary to the second operation.

The writer lays great stress on the control of the hemorrhage during the operation and has had excellent results with formaldehyde gelatin as a local hemostatic. The postoperative conditions are thus greatly improved and the drainage is more perfect than in cases in which the tube is constantly clogged by blood clots. It is also claimed that the secondary operation can be more readily carried out because the congested tissues no longer obscure the field and the necessary procedures can be more quickly done, with a consequent reduction in the amount of hemorrhage and shock. Postoperative toxemia is also eliminated, as the patient has had an opportunity during the preliminary period of drainage to fortify his normal resisting powers. The suggestion contained in Dr. Chetwood's paper is timely and sensible, and, although its value has been tested in only a small number of cases, there seems to be no good reason why it should not give equally good results in the hands of other operators.

EARLY OPERATION IN TRAUMATIC INTRACRANIAL HEMORRHAGE.

Very little doubt exists in the minds of surgeons as to the necessity of early operative interference in the presence of hemorrhage from the intracranial blood-vessels, and yet the diagnosis of the condition presents so many difficulties that many sufferers are not afforded this source of possible relief. The percentage of recoveries from expectant treatment is very small, and it is a matter of experience, as shown by autopsy results, that early resort to trephining would have been followed by success in many a fatal case. The absence of focal symptoms, even when the evidences of general and increasing cerebral compression are present, is considered by some surgeons sufficient reason for desisting from operation, because no definite information is afforded where the trephine should be applied. In most instances, however, a definite history of trauma may be obtained, and a careful examination of the scalp will reveal a contusion or abrasion as the desired guide. A good deal of uncertainty also exists regarding the condition known as cerebral concussion, which, it should be remembered, is transient in character. Many so-called cases of concussion are in reality cases of compression, and an earlier recognition of the true condition would result in operation while there is still a chance for relief.

A timely article by F. W. Murray, appearing in the *Annals of Surgery* for September, 1906, is one of the latest contributions to this subject. In this early operation is advocated, although the writer does not go to the extent of advising an exploratory operation in every doubtful case, as some extremists would do. The necessity of operating in hemorrhage from the middle meningeal artery is evident, but as regards the propriety of similar treatment in cases of subdural hemorrhage there is still some difference of opinion. As Murray states, and with justice, this view is inconsistent, for it is only rarely that the symptoms are sufficiently characteristic to allow of a differential diagnosis, and very frequently it is only by exploration that the source of the hemorrhage is ascertained. Whether extra- or subdural, the result of hemorrhage is always compression by the clot, and the sole indication of treatment is the removal of the clot and the checking of the bleeding. The important point is to recognize the presence of intracranial hemorrhage, and, if the symptoms of compression are severe, to relieve the compression immediately, no matter what the source of the hemorrhage.

The Use of Alcohol in Pneumonia.

The exact indications for the administration of alcohol in acute diseases, and even to a great extent the entire rationale of its behavior in the human body, are still far from being thoroughly understood. Medical opinion has already undergone several reversals in regard to this question, and the end does not yet appear to be in sight. It was only sixty years ago that a German physician was publicly accused of having caused the death of a patient ill with typhoid fever because he had administered wine to him, whereas, at a later period, the use of alcohol became so universal and indiscriminate as

no doubt to have caused the loss of many lives. This extreme attitude has now been abandoned, but there are still many pros and cons to this important question. Foch of Hamburg publishes in the *Münchener medizinische Wochenschrift* of October 30, 1906, the results of an effort he made to arrive at the consensus of opinion as to the use of alcohol in acute disease, taking as his example pneumonia. He directed a series of questions to a very large number of eminent physicians in Germany, Austria, Switzerland, Denmark, Sweden, and England. The answers received were sufficiently numerous to enable Fock to present a very interesting review of current opinion in Europe on this matter. The questions were the following: "Do you prescribe alcohol in every case of pneumonia, or only in special cases? In what form and in what quantity do you administer alcohol? Do you consider that it is necessary to give alcohol in pneumonia occurring in alcoholic patients? What effect do you expect from the administration of alcohol, and do you get it? Could this effect be obtained by the use of other measures?" As was to be expected, the answers received presented a wide disparity of opinion, and cannot be discussed in detail here, but it may be said that the majority of those questioned considered that alcohol should be given only in selected cases of pneumonia. The majority were also united in declaring for the advisability of not depriving alcoholic patients of all stimulant when suffering from pneumonia. There were many opinions as to the effect to be expected from the use of the drug, and very many of those questioned admitted that other remedies might be expected to give equally good results. Of especial interest were the statistics of the London Temperance Hospital, which is second to none in its cures of pneumonia, and yet in the four years from 1901 to 1904 reports the use of alcohol only 11 times in treating 297 cases of pneumonia. Many clinicians are of the opinion that while the use of alcohol may not be unfavorable to the course of the disease itself, the convalescence of the patients who have received it is more protracted than that of those who have not. This, of course, is very largely a matter of opinion, and is hardly susceptible of statistical demonstration since the patients receiving alcohol are apt to be the victims of the severest infections. Indeed, this whole inquiry of Fock's, while interesting as portraying the lack of uniformity in opinion among some of the most prominent European clinicians, does not help a great deal toward the solution of the problem. Definite results can be expected only when in large hospitals long series of cases are treated in strict rotation, first one with alcohol and the next without, of course making exceptions in cases in which the welfare of the patients seems to demand it.

Voluntary Dilatation of the Pupils.

The ability voluntarily to dilate the pupils is probably one of the rarest of physical endowments. It certainly has been very seldom recorded in medical publications, and Bloch, in reporting a case of this sort (*Deutsche medizinische Wochenschrift*, November 1, 1906), states that he was able to find in the literature only two references to observations of a similar nature. One of these is only a matter of hearsay, and the other was a patient of Bechterew's, who was able voluntarily to dilate widely the pupil of his right eye. Bloch's own patient was a young man under treatment for morphinism, and his power of pupillary control was discovered through the fact that the patient did not present the myosis customary to such individuals. In response to Bloch's inquiries, the patient stated that several years ago he had discovered that he possessed the power to dilate his pupils voluntarily, and on this and numerous subsequent occasions he gave demonstrations of his peculiar faculty. In order to perform the feat he would sit in the center of the room, with his head tilted backward and eyes directed toward the ceiling, that is, with the accommodation relaxed. Three to four seconds after the word of command a distinct dilatation of the pupils would take place, the apertures regaining their normal size at the expiration of about a quarter of a minute. The author relates various precautions taken in order to exclude all possibilities of intentional or unintentional deception on the part of the patient, notably the dilatation occurring on relaxing the accommodation, and then points out that if it is found that this ability to control the ciliary muscle exists to any extent, the current conception of the localization of the pupillary center must undergo revision. It is generally considered that the pupils are controlled either from the neighborhood of the corpora quadrigemina or in the medulla, that is, from a subcortical center. The ability voluntarily to initiate movements of the ciliary muscle not only connotes the power of voluntary motion in unstriated muscle, but also leads to the conclusion that for the pupils there must exist a cortical motor arc. The author closes by expressing the hope that this cortical center for pupillary control may at some time be discovered.

A Plan for Saving Infant Life.

When Alderman Broadbent, a brother of Sir Wm. Broadbent, the King's physician, took office as Mayor of Huddersfield, on November 9, 1904, he devised a novel scheme to reduce infant mortality. He offered to give parents living in a specified district of the city a guinea for every child born during his twelve months in office and living at the end of twelve months. The result of the experiment was announced recently, on the second anniversary of its inauguration. The rate of infant mortality in the Longwood district of Huddersfield, which is the experimental area, had averaged 122 per thousand for the preceding ten years. The period of the tests proved somewhat unfortunate. There were serious epidemics of whooping cough and measles, while the summer of 1906 was one of the deadliest recorded. The first baby to earn the gift was born on November 10, 1904, and the last on November 8, 1905. The mothers notified the managing committee of the births of these babies. No fewer than 107 received the gift. Four died and one did not claim the gift and its fate cannot be learned. If, however, it is reckoned as dead the average mortality works out 44 per thousand as compared with the previous 122 per thousand, certainly an astounding reduction.

The Army Canteen.

The canteen question will not down. In his annual report, made public in Washington some time ago, Brigadier-General McCaskey strongly urges the restoration of the canteen features of the post exchange at Oklahoma City. He says it is the belief of the men that the closing of the canteen is an interference with their personal rights guaranteed by the Constitution of the United States, and they ask that it may be submitted to the Supreme Court for final decision.

News of the Week.

The Annual Discourse at the Academy.—Thursday, November 15, being the fifty-ninth anniversary of the New York Academy of Medicine, the usual scientific character of the meeting of the Academy gave place, as is customary on these occasions, to the presentation of a subject interesting to laymen. This custom was initiated in order to show that the interest of the profession is not confined to medicine alone, but to subjects of general interest as well. Dr. Roswell Park of Buffalo gave a discourse on "Medicine and Surgery in Classic Art and Satire," which was accompanied by the presentation of over one hundred lantern slides. The necessity of a knowledge of anatomy had, from the earliest times, formed a bond between medicine and art. Raphael and Michael Angelo had made a study of anatomy, and Leonardo da Vinci had left an elaborate work on anatomy which had been plagiarized. The lantern slides consisted of illustrations of the works of great masters, having special bearing on the subject of medicine, the favorite subject seeming to be an anatomical demonstration by some famous physician before a class of students. Medicine in the past had furnished much material for the artist satirically inclined, and he hoped that the present and future would not furnish so large an opportunity in this devotion as had the past. At this meeting a painting was exhibited which had been presented to the gallery of the Academy. The president announced that the collection had been very fortunate of late in its acquisitions, and it was a matter of great satisfaction to the Academy.

Public Health Defense League.—About one hundred and twenty-five delegates, representing organizations in New York, Philadelphia, and cities of the South and Middle West, assembled in the Hudson Theater on November 16 under the auspices of the County Medical Society, and organized a society with the above title. Its object is to obtain and disseminate accurate information concerning practices and conditions of every kind that are dangerous to the public health and morals, and to work for the enlightenment of the public on all matters affecting these subjects. The society will also assist the authorities in getting evidence against violators of the public health laws, and will interest itself in securing legislation of this sort where it is needed. The meeting was called to order by Dr. Floyd S. Crandall, and Mr. Austen G. Fox was made chairman.

More Accommodations for the Insane Needed.—The fact that at present the State's institutions for the care of the insane are overcrowded, and that many individuals requiring institutional care cannot be provided for, was emphasized by Dr. William L. Russell, chairman of the Committee on the Study and Care of Defectives, in a report submitted to the State Board of Charities last week. He stated that altogether there are 2,500 such persons for whom no provision has been made. Statistics offered by the State Commission in Lunacy and the State Board of Charities show that on September 30 last there were 29,338 persons in the institutions for the insane, feeble-minded, and epileptic, of whom 26,357 were in the State hospitals, 1,946 in the institutions for the feeble-minded, and 1,035 at the colony for epileptics. It is said that the thirteen hospitals under the direction of the Commission in Lunacy have accommodations for 24,465 patients, and the total population on September 30 was more than 26,000. In the metropolitan district the greatest need of accommodations exists. At the close of the last fiscal year the four hospitals to which the insane of the metropolitan district are sent were badly overcrowded, and there are already about 2,000 patients belonging to the district in hospitals in other parts of the State.

A Second Institution for Dependent Epileptics in New York State.—At the seventh New York State Conference of Charities and Corrections held in Rochester, November 13-15, the urgent need for an institution for epileptics of a low grade of mentality was discussed, the suggestion being made that the Craig Colony for Epileptics at Sonyea should be reserved for patients whose minds have been but little or not at all impaired as a result of their disease. There are 16,000 epileptics in New York State, and we understand that there are at present about 1,000 applications on file at Sonyea from patients who cannot be admitted into the Colony because there is no room. The census of the Colony now is 1,050. Nearly 300 delegates to the Rochester Conference visited the Colony at Sonyea by special train on November 16, where they were provided with luncheon in Sonyea Hall, and where they later listened to addresses by Mr. Daniel B. Murphy, of Rochester, the newly-elected president of the Conference; the Hon. J. W. Wadsworth, Jr., Speaker of the Assembly, and Dr. W. P. Spratling. All were especially pleased to hear the Speaker of the Assembly declare himself forcibly in favor of a second institution in this State for low grade epileptics, and he promised, in case a bill to that end should be introduced into the Legislature, to do what he could to secure such an institution within reasonable proximity to New York City. There are sixteen great State Hospitals for the Insane. Why not more colonies or institutions for epileptics?

Census of the Blind.—The New York State Commission to Investigate the Condition of the Blind announces that it is greatly desired that the census of the blind in this State, which is now being taken, shall be as accurate and complete as possible. The purpose of this census is not only to determine the number of blind men and women who are phvsically capable of engaging in some of the occupations suitable for them, and to make recommendations to the Legislature concerning the establishment of industrial schools for the blind, but also to learn the cause of blindness in each case, in order that prophylactic measures may be instituted. The Commissioners will be grateful to any one who will send the names of blind persons, in order that they may be properly registered. The Commissioners are: Dr. F. Park Lewis, 454 Franklin street, Buffalo: W. J. McClusky, 425 Kirk Block, Syracuse, and Eben P. Morford, 512 Gates avenue, Brooklyn. The secretary is O. H. Burritt, Batavia, N. Y.

Seaside Hospital to Be Kept Open.—At its fortieth annual meeting held last week, St. John's Guild announced that it would keep its Seaside Hospital at New Dorp, Staten Island, open during the winter for use as a convalescent home for women and children. This is a new departure in the work of the Guild, which heretofore has kept open its floating and seaside hospitals during the summer months only. The committee on floating hospitals reported that during the summer season from July 5 to September 7, 1906, a total of 38,392 women, children, and babies were carried on the steamer *Helen C. Juilliard*. Of these 13,411 came from the East Side, 14,786 from the West Side, and 10,195 from Brooklyn. Patients to the number of 2,591 had been admitted to the Seaside Hospital,

and only 97 deaths had occurred there during the summer. The Treasurer's report indicated that more contributions were received in the year from October 1, 1905, to September 30, 1906, than ever before. Besides the annual appropriation of $20,000 from the city, more than $60,000, largely in small amounts, was received.

New Hospital Sunday Plan.—At a meeting of the Hospital Saturday and Sunday Association, held on November 12, it was decided to attempt to increase collections by securing offers of special gifts contingent upon results. By adopting this plan the trustees hope to increase the $95,000 collected last year to more than $100,000 this year.

Illinois Nurses Plan for State Registration.—Plans for a campaign for State Nurse Registration will be brought before the next session of the Illinois Legislature by the nurses of the State. The nurses are determined that in this case the proposed measure, which twice before has passed both Houses of the State Legislature, only to be vetoed by the Governor on account of technical defects, shall not fail for lack of due deliberation. The bill is now in the hands of an attorney, who is examining its provisions carefully, and who will report to the Association on its constitutionality and the probability of its passing.

Aid for Sick Pupils.—The Visiting Nurses' Association of Chicago has completed a profitable year of work among the school-children of the city. It has issued a report showing that hundreds of boys and girls have been cured of ills and returned to school as a direct result of the experimental campaign of investigation and visitation carried on by the nurses of the Association during 1906. A year ago the directors of the organization decided to appropriate $1,000 of their money to be used in sending nurses to the schools of the poorer districts for the purpose of bettering conditions among the boys and girls.

Two British Suggestions.—According to the daily press, the difficulty in determining just when objectionable sounds are to be regarded as a nuisance is to be dealt with by a British committee that will endeavor to standardize noise in some way, so that its intensity can be expressed in precise terms. The problem has been set by the Commissioner of the Metropolitan Police, who is troubled how to interpret the words "undue noise" which the regulations governing motor omnibuses prescribe. Lord Raleigh is to be one of the committee. The *Lancet*, in a recent issue, makes an appeal for the standardization of staircases as a needed reform. It gravely pictures the evils arising from irregularity in the height of steps, such as falls and toe-smashing against the edge, and contends that they should be everywhere of uniform height and breadth, and roomy enough for each step to accommodate the whole foot from toe to heel.

New York Skin and Cancer Hospital.—At the twenty-fourth annual meeting of the managers of this institution, held last week, the following officers were elected: *President*, J. Cleveland Cady; *Vice-President*, William C. Witter; *Secretary*, L. Duncan Bulkley; *Treasurer*, Alfred R. Kimball. The reports called attention to the necessity for increased accommodations for the hospital, and it was stated that many patients had to be turned away because of lack of room.

New York Orthopedic Dispensary and Hospital.—The Trustees of the New York Orthopedic Dispensary and Hospital announce that the Surgeon-in-Chief, Dr. Russell A. Hibbs, will give a course of clinical lectures on orthopedic surgery at the institution on Tuesday and Friday afternoons at 4 o'clock, from November 20 to December 21, inclusive. The course will be free to the medical profession and students.

To Stop Child Labor.—Senator Beveridge has announced his intention of introducing at the coming session of Congress a measure to prohibit child labor. This bill will provide that no railroad, steamship, steamboat or other carrier of interstate commerce shall transport or accept for transportation the product of any factory or mine that employs childen under fourteen years of age.

A Black List in Middletown.—The physicians of Middletown, N. Y., are reported to have compiled a list of the people who are able to pay their doctors' bills but do not do so, and have agreed, except in emergencies, to collect in advance from these persons before treating them.

The Sultan of Turkey is reported to be in a very precarious state of health, and Dr. Bergmann has again been summoned in consultation from Berlin. The details concerning the Sultan's illness, which is the result of enlargement of the prostate gland, were given by the Constantinople correspondent of the MEDICAL RECORD in the issue of September 8, 1906.

To Study Sleeping Sickness.—The French Geographical Society has collected the sum of $40,000 for the purpose of organizing a mission to West Africa to study the sleeping sickness in the French Congo. A central laboratory will be established in Brazzeville.

Consolidation of Medical Journals.—On January 1, 1907, the *Therapeutic Gazette, Medical Age*, and *Medicine*, all three published by E. G. Swift of Detroit, Mich., will be consolidated and issued in future as one journal under the title of the *Therapeutic Gazette*. The editors will be Drs. Hobart Amory Hare and Edward Martin, long associated in the editorial conduct of the *Therapeutic Gazette*.

Gift to the Yale Medical School.—At a meeting of the Yale Corporation in New Haven on November 19, a gift of $50,000 from an anonymous giver was announced to establish the John Slade Ely Professorship in the Medical School in memory of Prof. Ely, who died in the spring.

Dr. Theodore Schott of Bad Nauheim intends visiting the United States this winter for a stay of six or eight weeks. He will arrive in New York about the middle of January, and will, while in the country, read papers before societies in Boston, Cincinnati, and elsewhere.

Dr. D'Orsay Hecht has been appointed Assistant Professor of Nervous and Mental Diseases and Medical Jurisprudence in the Northwestern University Medical School, Chicago.

One Death in the Wesleyan Typhoid Epidemic.—One of the six students who contracted typhoid fever supposedly as the result of eating infected oysters at a banquet, has died.

Death of the Oldest Twin.—Last week what were supposed to be the oldest living twins were separated by death. They were brothers, living in Amsterdam and Syracuse, N. Y., respectively, and their age was ninety-one years. The deceased three years ago celebrated the sixtieth anniversary of his wedding. The death of an old lady on November 12 is reported from Danville, Pa., as the result of a cold caught on the occasion of the celebration of her one hundredth birthday a week before.

Immigration Increasing.—The report of the Department of Commerce and Labor, issued on November 15, shows a marked increase in the immigration statistics. In the six months ended October 31, 1904, the number of arrivals from all countries was 442,685, and in the corresponding period this year 632,137 immigrants landed at American ports, an increase of 45 per cent.

International Tuberculosis Congress.—At the fourth biennial session of this body, held at the Hotel Astor last week under the presidency of Dr. Daniel, the following officers were elected: *President,* Dr. C. H. Irion of New Orleans; *Vice-Presidents,* Dr. George R. Tabor of Texas, Dr. Charles Wood Fassett of Missouri, Dr. F. B. Fess of New Mexico, Dr. W. F. Drewry of Virginia, and Dr. J. W. McDonald of West Virginia; *Secretary-Treasurer,* Dr. M. M. Smith of Texas. Mr. Clark Bell was elected *Honorary President.*

Society of Medical Inspectors.—At a meeting of the Society of the Medical Inspectors of the City of New York, held on November 16, the advisability of further development of the medical inspection of school children was urged. A number of school principals discussed the effect of physical defects in retarding the progress of the pupils, and one speaker stated that nearly 95 per cent. of the children were suffering from eye affections, adenoids, or some other condition that impeded their mental and physical growth.

A Pure Milk Conference.—A public meeting was held in the hall of the New York Academy of Medicine on Tuesday evening of this week to consider the best means of insuring a pure milk supply. No definite conclusions were arrived at, but resolutions were adopted to do away with the prohibition of the sale of pure skim milk, urging the spread of information as to the importance of cleanliness in handling milk, recommending legislation making pollution of milk receptacles a misdemeanor, and insuring the separation of milk from other goods sold in groceries.

Southern Surgical and Gynecological Association.—The nineteenth annual meeting of this organization will be held in Baltimore on December 11, 12 and 13, 1906. The president is Dr. George H. Noble of Atlanta, the secretary Dr. William D. Haggard of Nashville, Tenn., and the chairman of the committee of arrangements Dr. Howard Kelly of Baltimore.

Rockingham County (N. H.) Medical Society.—At the second annual meeting of this society, held in Exter on November 8, these officers were elected: *President,* Dr. A. B. Sherburne of Portsmouth; *Vice-President,* Dr. J. J. Berry of Portsmouth; *Secretary,* Dr. Walter Tuttle of Exeter; *Treasurer,* Dr. Alice M. Chesley of Exeter; *Censor,* Dr. Charles A. Morse of Newmarket.

Æsculapian Society of the Wabash Valley.—At the sixtieth annual meeting of this society, held recently at Paris, Ill., the following officers were elected: *President,* Dr. Chas. B. Johnson, Champaign, Ill.; *Vice-President,* Dr. F. E. Bell, Mattoon, Ill.; *Secretary and Treasurer,* Dr. H. N. Rafferty, Robinson, Ill.; *Censors,* Drs. J. T. Montgomery, Charleston, Ill., C. E. Price, Eaton, Ill., Mark Rowe, Paris, Ill., W. E. Bell, Terre Haute, Ind., and T. E. Walton, Danville, Ill. Champaign, Ill, was chosen as the place for the semiannual meeting in May next.

Obituary Notes.— Dr. Allen L. Jenkins, a well-known physician of Plainfield, N. J., who was once mayor of that city, died suddenly of heart disease on November 13, at the age of sixty years. He was graduated from the New York Homeopathic Medical College in 1877. After practising for a short time in Connecticut, he returned to Plainfield, and had lived there ever since.

Dr. T. M. A'Heron of Hampton Junction, N. J., died of nephritis on November 15, at the age of sixty years. He was born in Ireland, and came to this country about thirty years ago. For many years he was a surgeon to the Central Railroad of New Jersey, and was well known for his skill in performing amputations.

Dr. Ferdinand Beach of this city died on November 15 in Santa Barbara, Cal., where he had gone about a year ago for his health. Dr. Beach was born in New Haven, and was graduated from the Yale Medical School in 1864, and served as an army surgeon from that time until the end of the Civil War.

Dr. W. A. Ball of Toronto, Ont., died on November 3, at the age of thirty-eight years. He was graduated from Trinity and University College eleven years ago, and had acquired an extensive practice in Toronto.

Dr. Asa Wall of Winchester, Va., died on November 10, at the age of seventy-six years. Dr. Wall was a surgeon in the U. S. Army during the war with Mexico and during the Seminole and other Indian wars. During the Civil War he served in the Confederate Army.

Dr. William Shafer of Camden, N. J., died on November 8 of heart disease, at the age of fifty-five years. Dr. Shafer was born in Leesburg, Va., and was graduated from Jefferson Medical College in the class of 1884.

Dr. Ossian Sumner of Providence, R. I., died on November 11, at the age of eighty-seven years. He was born in Ashford, Conn., and received his medical education at Jefferson Medical School in Philadelphia, from which he was graduated in 1844. He practised for a year at Pomfret and then removed to Providence, where he had practised ever since. He was made a member of the State Board of Pharmacy in 1870, and had held numerous other official positions.

Dr. Leopold De Rudder of Marcus, Wash., died on November 8, at an advanced age. He was a native of Belgium, and was educated in Brussels, but came to this country when a young man, and was surgeon in the Mexican Army during the war with the United States. In 1860 he entered the service of the U. S. Army and came to Colville as an army surgeon in 1872. When Fort Colville was abandoned in 1883 he began private practice, and had been engaged in active work until recently.

Dr. J. R. Mansfield of Wakefield, Mass., died on November 11 in Chelmsford. Dr. Mansfield was born in Carlisle, Mass., in 1832, and after serving as surgeon in the Civil War he settled in Wakefield, and had been engaged in active practice until a few years ago.

Dr. J. T. Reeve of Appleton, Wis., died on November 5, at the age of seventy-four years. Dr. Reeve was born at Goshen, N. Y., and was a graduate of Jefferson Medical College, Philadelphia. He had practised in Wisconsin since 1855, and for nineteen years was secretary of the Wisconsin State Board of Health; he also served several terms as president of State Medical Society.

Dr. H. H. Rodman, formerly of this city, died suddenly in Buffalo on November 12. He was graduated from the College of Physicians and Surgeons in the class of 1896.

OUR CANADIAN LETTTER.

(From Our Special Correspondent.)

DEATH OF DR. JAMES STEWART OF MONTREAL [illegible] MEDICAL ASSOCIATION PROVINCIAL [illegible] EXHIBIT —MEDICAL INSPECTION OF MONTREAL SCHOOLS—CONSUMPTION OF ALCOHOLIC STIMULANTS IN CANADA [illegible] OF DEPENDENTS AND DELINQUENTS [illegible] IN CANADA.

[illegible], November [illegible], 1906.

The death of Dr. James Stewart of Montreal has removed one of the greatest names from the list of Canadian physicians. He had a distinguished career. Born in 1846, he studied at McGill University, where he graduated with honors in 1869. He subsequently studied at Edinburgh, Vienna, Berlin, and London; in fact, he was always a student, and nearly every year went to Europe and spent some time at the hospital centers. He began the practice of his profession in a small country hamlet, where his qualifications were so recognized that his eminence brought to the little village the greatest fame it ever had before or since. He was beloved by all his professional confrères, and the field of his work became very extensive. He declined all invitations to leave the country for the city until 1883, when the chair of Materia Medica at McGill was offered to him. Then he reluctantly left the field of country practice to enter upon the duties of the professoriate in Montreal. During the whole of his career he did special and valuable work in nervous diseases, and after taking up his residence in Montreal he became recognized as probably the best Canadian authority in that department of medicine. His whole life was devoted to work. His observation was exceedingly acute, and it was often remarked that he gathered more information with the eye than most men could by a complete examination of the patient. His clinics were certainly unsurpassed in Canada, and were always greatly appreciated by the students. He deprecated shotgun prescriptions made up of many ingredients. "Never give a drug," he would say, "unless you have a very good reason for doing so, and then give sufficient to be of some use, and give it in the simplest way you can." He was for several years before his death Professor of Medicine at McGill. His acuteness at clearing up a diagnosis made his skill in great demand. His kindly disposition was coupled with a most retiring manner. On the opening of the Royal Victoria Hospital, Dr. Stewart was unanimously selected for the position of physician-in-chief, and so continued until his death. His chief medical works were "Treatment of Heart Affections" and a textbook on "Nervous Diseases." Besides these he wrote numerous papers for English, American, and Canadian medical journals. He was a past president of the Canadian Medical Association and did excellent work on its behalf. Dr. Stewart had been ill for about two years, but the final illness lasted little more than a week. An apoplectic shock was the immediate cause of death.

The Winnipeg Medical Association has held its annual meeting and elected the following officers: *President*, Dr. E. W. Montgomery; *First Vice-President*, Dr. J. R. Davidson; *Second Vice-President*, Dr. N. J. McLean; *Secretary-Treasurer*, Dr. C. H. Vrooman; *Councillors*, Drs. McKinty, A. MacKay, Galloway, and Todd. Judging from the interest manifested at the annual meeting, the association has entered upon a year with promising results.

The Ontario Government has decided to take practical action with a view of educating the people of the province in regard to the nature of tuberculosis and the means available both for its cure and its prevention. The tuberculosis exhibit which was made under the auspices of the Canadian National Sanitarium Association during the meeting of the British Medical Association at Toronto in August is to be duplicated, and arrangements are now being made by the Provincial Board of Health to have this exhibit open for a certain number of days in each county in Ontario. The exhibit will in this way reach, and doubtless benefit, every portion of the country. This marks a new step in the great forward movement to educate the people in regard to the nature of the disease and the simple but effective methods by which tuberculosis can be prevented. The bold action taken by the Ontario Government in this matter is certain to bring about results that could not be easily accomplished without such influences behind them. The Provincial Secretary of Ontario, Hon. W. J. Hanna, has, by deciding to take action in educating the people of Ontario in regard to tuberculosis, shown himself to be favorable to medical progress. The exhibits are now being arranged for in such a way that all the cities and county towns will be given the advantages of these free exhibits, with the series of lectures that will accompany them.

The medical inspection of schools has been established in the city of Montreal, where there are 175 schools, with a school population of 150,000 children. Forty medical practitioners were recently appointed by the City Council to carry on the work. One inspector, in presenting his first report, gives many reasons why the work should be diligently carried out. These reasons speak of "thirty pupils out of a class of sixty-six, attacked by measles, as the result of one pupil suffering from measles attending that class; schools suffused by stenches from civic dump heaps; 15 per cent. of pupils at one school suffering from defective eyesight; 15 per cent. of pupils at another school suffering from tumors, which are disclosed by a simple examination at first sight, and which are the cause of serious throat troubles. These tumors predispose the pupils to diphtheria and reveal their presence by eruptions on the face. We found a school in a basement, where the light is defective, the air bad, and humidity permanent; a school beneath the basement of a church; temporary accommodation at one school to deceive the medical inspector; forty pupils crowded in one classroom where the cubic contents of air should barely suffice for fifteen; large numbers of pupils showing signs of tuberculosis and insufficient nutrition." With such conditions reported there is every reason to expect that the system of medical school inspection will produce good results. The citizens of Montreal have set an excellent example to other Canadian cities in thus protecting the lives of the children, and a determined effort is likely to be made that will prove a blessing, the value of which it would be difficult to estimate.

A recent Government return shows that the per capita consumption in Canada of alcoholic liquors and tobacco during the year ending June 30, 1906, was as follows: Spirits, .927 gallons; beer, 15,.660 gallons; wine, .6989 gallons; tobacco, 2.991 pounds. This report shows a decrease in the quantity of spirits and an increase in beer, wine, and tobacco compared with previous years. The duties paid were at the followig per capita rate: Spirits, $1,939; beer, $2.46; wine, $0.54; tobacco, $1,135. Dr. G. Bourgeois presented a report to the recent Congress of French-speaking physicians in which he gave some striking details of alcoholism, indicating that, as compared with other countries, Canadians are a temperate people. In the Province of Ontario there is one "bar" for every 815 people; in the Province of Quebec, one for every 1,045 people; and in New Brunswick, one for every 1,898 people. Full and interesting discussions followed a paper presented by Dr. Triboulet of Paris on "Alcohol as a Causal Influence of Tuberculosis." As a result of these discussions the following resolutions were adopted by the Congress: (1) The surest method of doing away with alcoholism in Canada would be to pass a law prohibiting the manufacture and sale of all distilled alcoholic liquors in the Dominion of Canada, save for therapeutic and industrial purposes. (2) If for political or other reasons, this proposal cannot be realized, it is desirable that the Provincial Government should undertake to carry on the liquor traffic. (3) Should the Provincial Government refuse to take over the liquor traffic, a charter should be granted to a private company in each province which would take charge over the liquor traffic on the express understanding that the company was to pay to its shareholders only a fixed dividend of a moderate amount, and the surplus profits were to be devoted to charitable philanthropic or other purposes to be designated by the Provincial Government. (4) Should none of these proposals be accepted, the Congress recommends to the legislatures to amend the liquor license act by limiting the rights and privileges of municipal councils in such a way as to permit them to grant only one liquor license per 1,000 of population. The attitude taken by the French-speaking physicians of the Province of Quebec at their recent Congress is favorably commented upon, for it furnished a reliable expression of opinion on a subject which is receiving considerable attention in Canada at present.

Stringent measures have recently been inaugurated by the Ontario Government to deport all delinquents and dependents who have resided in Canada for less than two years. Already a large number of immigrants have been returned to the European ports, and a careful inquiry is being made to ascertain the number of patients in the hospitals for the insane who have had less than two years' residence in this country. For several years there has been evidence of the fact that in the large immigration to Canada there were many who soon became a public charge and whose maintenance had to be provided for in public institutions. Strange to say, there was considerable hesitation in taking the steps which are now being taken to have such persons returned to their homes. One of the results will no doubt be that steamship and railway com-

panies will be more careful when they understand that the undesirable immigrants brought over have to be returned free by the transportation companies. Those coming from the United States are also returned to their homes, for as a result of a recent census it was quite manifest that in the public institutions of Ontario there were many American citizens being cared for who had resided in Canada for less than two years.

There have been several football fatalities in Canada during the past few weeks; in fact, so frequent have been these unfortunate occurrences that it is now suggested that the game should be prohibited. The university campus at Toronto has been the scene of numerous accidents, and two young men who went into the game there in apparently the best of health were fatally injured. Montreal, Ottawa, and Kingston have each reported serious accidents. It is said that last year in the United States twenty-eight students were killed and over 1,000 more seriously injured at football. Canada this year is certainly contributing its full share to the fatalities of the sport. Considering the numbers engaged, the casualty list is greater than in the late Russo-Japanese War. It is now seriously felt that a game with such a record should have no place in college life, and its total banishment from the campi of Canadian universities will not cause much surprise or any long-continued regret.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HYGIENE AND FOOD SUPPLY—DILATATION OF THE HEART—BACTERIOLOGY OF ASEPTIC WOUNDS—CLINICAL EXHIBITS—THE VIVISECTION COMMISSION—FEEBLE-MINDED COMMISSION TO REPORT ON LUNACY.

LONDON, November 2, 1906.

A PUBLIC meeting convened by the National Health Society was held on Monday, with the object of drawing attention to the need for further measures to guard the food supply of the country. Sir F. Treves took the chair and, remarking that the society had for years preached to deaf ears, but it was to be hoped that for once the public would listen, urged the importance of the food supply, as it affected everyone personally and acutely. This supply was spoken of as good, but much uncertainty existed as to whether it was wholesome, untainted, and incapable of communicating disease. As the bacillus of typhoid was not visible to the public, they did not seem to mind swallowing it by the thousand. The matter touched the diminishing birth rate at one end and the infant mortality at the other. The treatment of our meat before we ate it was no advance on that of the cave dwellers. It was said that cooking destroyed all germs, but that was no reason for throwing meat on the floor. Our neglect was being paid for by ill health, disease, and death. He paid a cordial tribute to the work of the medical officers of health, but those gentlemen would agree that their inspections were carried out at the wrong end—at the finish instead of at the source. He quoted certain statements from the last report of the medical officers for Stepney and declared such things could only be remedied by an aroused public opinion.

Sir J. Crichton-Browne referred to a meeting held a few days previously, when it was declared that recent revelations about canned meats had only the flimsiest foundation, and that on the whole they were as nutritious as fresh meat. He disputed these statements. Properly prepared canned meats were palatable, wholesome, and nutritious, though not so nutritious as fresh. It was most desirable they should be subjected to inspection—as, indeed, should all perishable foods. Imported foods should bring with them a public warranty from the country of origin, and also be tested at the port of entry. Inspection must be of a highly technical and skilled character if the wiles of the adulterator were to be circumvented. Private slaughter-houses should be abolished and the London Act which penalized the sending a diseased carcass to market should be extended to the whole country. The adulteration acts worry the retailer, but let the real culprit go scot free. A resolution was adopted demanding further protection of our food, particularly meat, milk, preserved foods, and shellfish.

At the Medico-Chirurgical Dr. A. M. Gossage read a paper on "Dilatation of the Heart," advocating almost exclusively the myogenic theory. The action of the heart being of muscular origin, he attributed dilatation to diminished tone of the fibers of the muscle, though he admitted that tonicity might be affected by nervous or other influences, and that in either direction. Thus it would seem that those who do not accept the myogenic explanation have foundation for their scepticism. Dr. Gossage credited the cardiac muscle with the power of rhythmically building up excitability, conductivity, contractility, and tonicity. He adopted the view that the contraction started from the great veins, but he had to admit that it is possible under artificial stimulus that it may begin in the ventricles. Dilatation, he held, was due to diminution of tonicity and was associated with increased excitability, and also, perhaps, contractility. Drugs which increase tonicity are followed by a reverse condition. With loss of tone the ventricles become the more excitable part and extra systoles ensue, and if this loss become excessive, the stimulus is greater still in the ventricles, and from them the rhythm starts.

In discussing the paper, Dr. A. Morison remarked that more than one factor was concerned in any organic action, and in loss of tone the blood supply and innervation had to be considered. The most constantly rhythmic organs had the most nerve supply. He could not accept the myogenic theory as altogether sufficient.

Dr. E. I. Spriggs referred to mechanical factors as the load on the ventricular walls in bringing on dilatation, and said he would like some proof of extra systoles starting in the ventricle.

Dr. John Hay mentioned the new point of the paper, viz., that when tone increased, other functions decreased. It was doubtful whether tonicity was of the same nature as contractility. He cited the effects of infusing sodium and digitalis.

Professor Wenckebach accepted the myogenic theory in full. Was the stimulus for contraction given by nerves or the cardiac muscle? The properties of the latter were known and could be acted on. No proof was forthcoming that tone and rate were interdependent. The relation of tonicity to contractility was not known.

This discussion seems to show that physiology has yet more to investigate on the points considered.

At the Medical Society "The Bacteriology of Aseptic Wounds" was the subject of a paper by Drs. Dudgeon and Sargent. The staphylococci were spoken of a good deal. In fifty aseptic wounds, most of them operative, no chemical antiseptic having been used in forty-five, the authors found in these forty-five the wound was sterile in twenty-six. In the other nineteen the *Staph. albus* was present in fifteen. In six of the forty-five the skin was sterile. In only one of the whole fifty cases was there suppuration, and in that the *S. aureus* was found. In all there was some pyrexia after operation which they thought due to *S. albus*. They suggested that this might play a physiological part.

Mr. Lockwood considered any wound containing bacteria to be septic. He used carbolic acid, but only one in sixty, and thought chemical antiseptics indispensable in London.

Mr. Spencer thought there was no proof of such distinction between *S. albus* and *S. aureus*, as suggested in the paper.

Mr. Malcolm said the *S. albus* was not always present, and therefore could not be physiologically necessary in healing wounds, and inflammation sometimes had a chemical origin.

Mr. Leedham-Green described experiments with pure metals as sutures, etc. Copper was the most powerful bactericidally, silver and iron being both much weaker.

At the Clinical Society there were many interesting exhibits. A case of traumatic cephalhydrocele in a female infant of six weeks which he had treated by operation was shown by Mr. Drew. The baby was admitted to the hospital within a few hours of accident with a large swelling on the right side of the head. There had been no loss of consciousness. For two days after admission there was twitching of left arm and leg and impulse in the swelling when the child cried. The tumor increased and the gap in the bone widened to about one-half an inch. At the operation the sac was found to be formed by separated peritoneum. On letting off the fluid profound shock ensued. The fracture was in the parietal, one-half inch across, and through the center hernia of brain protruded. This was cut off, the bones drawn together with silver wire, periosteum replaced, and the wound sutured. Mr. Godlee congratulated Mr. Drew, and remarked on the rarity of success in such cases.

Another brain case was a child of four years and ten months admitted to the Children's Hospital with symptoms of cerebellar tumor. Mr. Ballance operated in June, 1905, and removed the large tumor shown. Good recovery followed.

Dr. Garrod showed a case of alkaptonuria. A girl of three was the patient, and no other case had been known in the families of her parents who were not related. The condition seems more rare in females than in males, only

six or seven cases in girls being recorded out of a total of about forty congenital cases.

Several bone cases were exhibited, *e.g.* traumatic separation of the head of the femur, as shown in a skiagram. Malunited fracture of both bones at the ankle joint treated by operation. Deformity of the long bones in a girl of eight. Skiagrams seemed to show that the chief deformities were due to fractures and irregular ossification at short distances from the epiphyseal lines. Mr. Clutton, president, thought the case was one of rickets, and still progressing; he found fragilitas ossium often due to rickets. Another bone case was in a girl of seven, who was noticed to limp thirteen months before admission to hospital, when the right leg was two and one-half inches shorter than the left. The shafts of femur and tibia were thickened, chiefly at their ends. Some thought the disease syphilitic. Another child of eight, boy, who had dysentery when seven weeks old, followed by swelling of right knee, which lasted two months, a year ago walked with peculiar gait, resembling that in congenital dislocations. No pain, no tenderness, joint movements free. The trochanters were raised, especially the right, prominently so on adduction of legs. A member compared the case to septic arthritis in adults after dysentery. They were often of long duration. A case of double coxa vara with possible fracture of neck of right femur, as seen in skiagrams, was shown in a boy of sixteen. A barrow fell on him in August, 1905, and broke his right thigh. The trochanter was more prominent than the left, and was three-fourths of an inch above Nelaton's line. Both limbs rotated outward; abduction and adduction much limited; walking difficult, and the gait that of coxa vara. The lad said his toes had always turned out, but he was active and could join in games up to the time of his accident.

The antivivisectionists are angry with the Royal Commission for deciding to hold its meetings in private and have protested that the press must be admitted and the witnesses cross-examined by counsel in order to elucidate the truth. Mr. Stephen Coleridge said he was most anxious to be examined and cross-examined. Poor fellow, his appetite for notoriety seems unappeasable.

The Royal Commission on the care and control of the feeble-minded have been entrusted by an extension of their terms of reference with the additional duty of inquiring into the constitution, jurisdiction, and working of the Commission in Lunacy and of other lunacy authorities, and into the expediency of amending the same or adopting some other system of supervising the care of lunatics and the mentally defective, and of reporting as to any amendments in the law which should, in their opinion, be adopted. This great addition to the duties of the Commission may well be the forerunner of a complete reform of our lunacy laws and their administration.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

WHERE, WHEN, AND HOW CAN AMERICAN PHYSICIANS OBTAIN POSTGRADUATE INSTRUCTION IN GERMANY?

BERLIN, [illegible]

In Berlin there are three organizations for postgraduate study, the first of which is the *Dozentenverein für Ferienkurse*. These courses are held twice a year, in the months of October and March. In case Easter comes in the month of March the courses are held in April. These courses are given by the University *Dozenten* and their assistants, and are noteworthy for their variety and excellence. For example, to mention a few subjects, normal and pathological anatomy is taught by eighteen instructors, internal medicine by forty-one, neurology by seven, surgery by ten, ophthalmology by six, rhinology by ten, gynecology by eight, and skin and urinary diseases by ten. In addition lectures are held on physiology, forensic medicine, hygiene, chemistry, radiotherapy, and scientific photography. Information regarding these courses may be obtained from the office of the Langenbeckhaus, Ziegelstrasse 10. Another organization for the same purpose is the *Vereinigung zur Veranstaltung von Kursen für praktische Aerzte*. This is much smaller than the previous one, but possesses the advantage that its courses are given throughout the entire year, beginning with the first of every month. Its members are seventeen laboratory and clinical workers, who give instruction in bacteriology, internal medicine, massage, psychiatry, surgery, ophthalmology, rhinology, otology, gynecology, urology, dermatology, and disorders of speech. Correspondence for the association is conducted through the book store of Oscar Rothacker, Friedrichstrasse 105. The third organization is the *Verein für ärztliche Fortbildungskurse*, and is in general very similar to the preceding one. Under its auspices courses lasting four weeks are given every quarter, including all medical branches. The business address of the organization is care of the book store of Otto Enslin, Karlstrasse 32. In addition, once or twice every year practical courses in bacteriology are given in the Königlichen Institut für Infektionskrankheiten. These cover bacteriological technique, with especial reference to modern methods in dealing with domestic and tropical diseases, as well as the subjects of immunity and the specific treatment of infectious diseases. The entire course consists of fifty lectures requiring from one to one and one-half hours a day, and of practical laboratory work. Besides these facilities for postgraduate work, a great many of the directors of municipal or governmental institutions, laboratory workers, chiefs of clinic, etc., give courses at any time when they can secure a sufficient number of participants. In general three to four persons are sufficient to form a class.

In Greifswald there is an association for postgraduate study. The courses comprise only the chief branches, and usually are held in the last week of July and the first part of August. The president and secretary is Prof. Dr. Martin, Greifswald.

In Halle a series of courses is held during the first two weeks of August in the institutes of the university. All of the chief subjects are taken up. Address, *Vereinigung für aerztliche Fortbildungskurse*, Halle.

In Marburg postgraduate courses in surgery, pathology, anatomy, ophthalmology, and internal medicine are held in the university from the middle of August to the end of September.

In Munich postgraduate work can be done in the university buildings during the autumn vacation, from the middle of September to the middle of October. The subjects in which courses are held are anatomy, pathology, bacteriology, physical therapy, clinical chemistry, children's diseases, internal medicine, rhinology, hygiene, dermatology, surgery, gynecology, and ophthalmology. Address, Dr. Kerschensteiner, Ziemssenstrasse 79.

In Erlangen and in Würzburg there are associations for postgraduate study which usually hold their courses in September. Correspondence should be addressed to Privatdozent Dr. O. Schulz, Erlangen, or to the Universitätsquästur, Würzburg.

In Dresden courses are held in the Königlichen Frauenklinik during May, November, and February. In addition, during the summer and winter terms clinical instruction is given daily. Inquiries should be addressed to the Direktion der Frauenklinik, Dresden.

In Leipsic there is an association for postgraduate study which gives courses in ophthalmology, internal medicine, bacteriology, pediatrics, urology, otology, dermatology, and surgery, usually during the month of August. Information may be obtained from the Universitätsquästur, Leipsic.

In Jena postgraduate courses are held during July in the following subjects: psychiatry, gynecology, internal medicine, surgery, ophthalmology, otology, rhinology, hygiene, bacteriology, and pharmacology. Information may be obtained from Prof. Dr. Gärttner, Jena.

In Hamburg during November postgraduate instruction is given in the Eppendorfer Krankenhaus in internal medicine, nervous diseases, surgery, ophthalmology, gynecology, pathology, rhinology, otology, massage, Roentgenology, urology, dermatology, hygiene, and forensic medicine. Courses are also given in the Seemanns Krankenhaus und Institut für Schiffs und Tropenkrankheiten during the months of April, May, June, October, and November. These are especially intended for ships' surgeons and deal with tropical diseases and allied subjects. Correspondence should be directed to Prof. Dr. Nocht.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

VESICAL CALCULUS—SUPRAPUBIC LITHOTOMY—CASE OF THE SPLEEN—[illegible]—CHRONIC PANCREATITIS—[illegible]

VIENNA, [illegible]

Dr. Hugo Unterberg has recently operated on several unusual cases of vesical calculus. The first patient was a man of twenty years, who complained of urinary dribbling and severe pain in the bladder region. A stone present in the membranous urethra blocked the lumen so completely that not even the thinnest sound could be passed beyond it. The Roentgen rays were resorted to in order to determine whether stones were present in the bladder also, and two calculi were revealed. A suprapubic cystotomy was therefore done. The second patient was a man sixty-seven years

old, who exhibited the typical picture of stone. Cystoscopic examination revealed the presence of numerous calculi, arranged in two rows behind the moderately enlarged central lobe of the prostate. Forty-nine uratic concretions were removed by the suprapubic operation. In the first case an exact diagnosis would have been impossible without the Roentgen rays, and in the second the operation was much facilitated by the cystoscopy. Unterberg sutures the bladder completely only in those cases in which pure urate or oxalate stones are present; if there are phosphatic calculi, the vesical incision is not closed entirely, but is drained in the suprapubic region. The same operator has recently had an interesting case of renal calculus. This patient, who was thirty-five years old, had for some years complained of pain in the left side. On making a cystoscopic examination, it was found that the bladder was the seat of a diffuse cystitis, and that the left ureteral orifice was dilated, while the right one was normal. The left kidney was functionally inefficient, and at the nephrotomy a well-marked perinephritis was revealed. The exposure of only a part even of the convexity of the organ was attended with considerable difficulty, owing to the density of the adhesions. On opening the pelvis, which was much dilated, five stones were removed. The patient made an uncomplicated recovery.

A puerperal strangulation of the spleen has been treated by Prof. Barsany. The twenty-six-year-old primapara presented the symptoms of a severe peritonitis, owing to torsion of the pedicle of a wandering spleen. On admission she had a high temperature and 17,000 leucocytes, so that a tentative diagnosis of suppurating ovarian cyst was made. Some weeks later the fever had subsided and Barsany opened the abdomen. Fifteen liters of pus were evacuated from an enormous cystic swelling, while near the lumbar vertebræ the necrotic spleen with its twisted pedicle was found. The organ was extirpated, and the abscess cavity was flushed out and drained, after its wall had been sutured to the abdominal wall. It was supposed that the spleen became freely movable after an attack of malaria, and that its pedicle became twisted in the course of the pregnancy, producing hemorrhage into its capsule, which was followed by infection from the intestine and gave rise to the enormous abscess, although the condition might have been pyemic in origin.

Ernst Fischer successfully treated a perforating wound of the lung, caused by a stab from a pocket-knife, in a woman thirty-two years old. The wound was four cm. in length, on the left side of the thorax, and a thick stream of blood mixed with air poured out. On extending the skin wound, it was found that the wound, which traversed the eighth intercostal space, did not involve the costal arteries. Ten centimeters of the ninth rib were resected and the pleural wound extended; the lung was drawn out and was found to present a wound six cm. deep, from which arterial blood was flowing. The hemorrhage was promptly controlled by five catgut sutures and the pleural cavity drained. Complete recovery followed in five weeks.

Koloman Bauer has succeeded in obtaining from ox blood an active ferment in solution which in a period of three days is capable of chemically decomposing 83 per cent. of the uric acid added to it. The fermentative capacity is greater when the amount of uric acid added is comparatively small. If the ferment is peptonized or undergoes other destructive changes, it loses its potency. There is but little evidence that ferments entering the body from without retain any activity, and experiments in this direction can be regarded as successful only if the foreign ferments can be rendered resistant to gastric digestion.

Bencse has observed a case of chronic syphilitic indurative pancreatitis. The diagnosis of chronic atrophic hepatitis had been made four years previously on the thirty-seven-year-old patient. Recently she had presented emaciation, diarrhea, small spleen, no ascites. There were six or eight stools a day, the feces being gray in color and fatty. The urine contained 8 to 10 per cent. of sugar, and three to fourteen liters a day were voided. The administration of one hundred grams of butter gave rise to lipuria, butter floating on the surface of the urine. The patient died in consequence of gastric and intestinal hemorrhages. The symptoms pointed toward involvement of the pancreas, probably diffuse, as catarrh and impaired meat digestion were present, and with probably destruction of the cells of Langerhans. The syphilitic nature of the condition was probable, owing to the presence of enlarged cervical lymph glands, and as one pregnancy had terminated in a still birth and the other in an abortion. The diagnosis was confirmed at autopsy.

Balas has resorted to iodoform wax in order to fill the cavity left after exenteration and total removal of the orbital roof. The patient was a man forty-one years old, whose right eye had been removed two years before, owing to the presence of a new growth, which recurred and caused intense pain. The entire orbital cavity was cleaned out and the new growth removed, together with the roof of the orbit, which had to some extent been eroded by the tumor. Two days later Mosetig's iodoform wax was employed in the following way: The cavity was first disinfected with concentrated formalin solution, and then the warm iodoform-oil-wax emulsion was poured in. After it had congealed the eyelids were united over it. Healing was uncomplicated.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 8, 1906.

Achylia Gastrica.—F. W. White gives a general description of this condition, basing his observations on nine cases of the disease seen in 235 consecutive cases of chronic disease of the digestive organs, in which number there were forty-one cases of subacidity. He therefore regards the simple achylia gastrica as a relatively common condition. The symptoms are not characteristic, and the diagnosis must be made from the physical examination of the patient, and of his stomach contents and feces. Those cases are best classified as achylia (although not such in the strict sense of the word) in which there is an entire lack of HCl secretion, but in which very minute traces of pepsin or rennet are retained. In making the diagnosis of gastric cancer we should remember the frequency of simple achylia, which may resemble it closely. The examination of the feces for invisible blood is, under these circumstances, especially useful. The etiology of simple achylia is unproved; its course suggests a functional origin. Its most satisfactory treatment is hygienic and dietetic.

The Analytic Method in Psychotherapeutics.—H. Lilienthal and E. W. Taylor refer to efforts made at the Massachusetts General Hospital to systematize methods of mental treatment. Those familiar with neurological hospital patients know that very many of them do not require the use of drugs or mechanical means of treatment, but rather analysis of the disordered mental state and the treatment of the condition based on the results of such an analysis. Two illustrative cases are given illustrating the methods followed. Thus in one case regarded as hysterical aphonia in which the usual therapeutic procedures gave but transient relief, it was found that the patient was in a condition of deep despondency, owing to the insanity of a brother who was confined in an asylum. The patient, a young woman, was finally induced to tell the whole circumstances of her brother's case, and measures were taken to relieve her mind of the popular prejudice existing about insanity. She was given to understand that insanity is a misfortune and not a crime, that there is no more shame connected with it than there is with physical disease. Moreover, the condition was fully analyzed to her, and in simple language she was given to understand how her trouble originated. The aphonia never returned after the first explanation, and, although she came regularly to the clinic for several months, she did not lose her voice once. On one or two occasions she came in with hoarseness, but no loss of voice. The condition cleared up completely, and now, after ten months, the patient is well and considers herself cured. The authors believe that the application of the analytical method is perfectly practicable, and that in the greater majority of cases a little perseverance will accomplish the desired results. The patients themselves quickly learn to realize the value of the suggestions made to them in the course of the analysis of their conditions, and appreciate also the time given and the effort made by the physician in their behalf.

New York Medical Journal, November 10, 1906.

Surgical Treatment of Certain Lesions of the Upper Abdomen.—J. B. Boucher refers to certain conditions in which surgical intervention is now recognized as the proper procedure. He discusses the symptomatology of gallstone disease, and chronic dyspepsia, which so often leads up to ulceration or is confounded with it. He believes that it is often difficult, and at the present time impossible to draw a hard and fast line which shall divide the cases into those in which medical, and those in which surgical aid is indicated. The author says that many patients with the first attack without serious hemorrhage, who can give up the time and who realize the importance of prolonged rest, will recover permanently under medical treatment, but the

following types should be considered surgical: (a) Cases of relapsing acute hemorrhage; (b) cases with persistent hemorrhage causing anemia; (c) perforations; (d) recurrent ulcer, pure and simple, attended with dyspepsia and starvation; (e) pyloric obstruction; (f) adhesions following ulcer or independent of it; (g) scar contraction of body of stomach giving hour-glass condition; and (h) some cases of intractable dyspepsia originating in an ulcer and for which the definite pathology is unknown.

Appendicitis: a Plea for Early Operation in Pus Cases.—W. D. Ward gives the histories of a series of cases, showing the change which has occurred in general surgical opinion regarding the advisability of early intervention in appendicitis. He is opposed to the Ochsner method. He notes the low mortality in general, acute, and also in the interval cases, but declares that the mortality is still too high in those cases in which the appendix has ruptured, and in which pus is present about it either as a circumscribed abscess or as a general peritonitis. Delay or incomplete work in such cases means that there may result subphrenic or hepatic abscess, pylephlebitis, splenic abscess, and infections in various parts of the body. The author declares that in a pus case after incising the abdominal wall we should carefully place gauze sponges so as to separate as effectually as possible the infected areas from the uninfected, then evacuate the pus first with mops, then by a local irrigation, free from the appendix, and remove it, then separate the adherent coils of large and small intestine, evacuate all secondary pus pockets, wipe the lymph from the intestines, and make them as clean as possible, remove the protective gauze pads, and put in fresh ones for drainage. Take the greatest possible care, he says, in placing drains, build up as it were a wall of gauze which will hold the intestines away from the infected areas, and then use central ropes of gauze to drain the infected spots; leave the abdominal incision wide open, no sutures. If, after the separation of adhesions, it is found that the inflammation has already spread beyond the boundaries of the right iliac fossa, a second irrigation should be given according to the following rules: Use a large tube at least three quarters of an inch in diameter; hold the funnel high so that there is plenty of force; turn the patient on the right side, and keep two fingers of the left hand spread wide apart in the incision, so that the exit is very free, and use at least two or three gallons of water. An irrigation given in this way does not spread pus, it cleanses. In these cases of general peritonitis use the Fowler position and Murphy's method of continuous saline infusion by rectum.

The Importance of Early Recognition of Nasal Obstruction and Its Relation to Later Respiratory Disturbances.—F. A. Faught calls attention to the importance of the nasal functions of warming, moistening, and purifying the inspired air. If these results are not properly attained, the lungs are bound to suffer. Children who breathe imperfectly at night or who seem dull and backward at mental development should be thoroughly examined. The author enumerates the lesions which in varying combinations are found in these children. In spite of the prevalence of adenoid disease in the pharyngeal vault and the abundant opportunity offered for its study, we are still in doubt as to its true underlying cause. Ultimately the chronic rhinitis and disturbances of aëration give rise to ear complications. The author describes the appearances of the parts as seen in routine examinations, enumerates the symptoms of the various lesions, and gives suggestions as to treatment. The paper brings forward nothing new.

Journal of the American Medical Association, November 17, 1906.

Utilization of the Broad Ligaments.—E. C. Dudley describes the mechanism of descent of the uterus, pointing out the importance of restoring the normal axes of the uterus and vagina and the preservation of the pelvic floor. In complete prolapse of the uterus the condition is practically a hernia, and should be treated like other hernias by reducing it and excising the sac in such a way as to expose strong fascial edges, which should be firmly united by sutures. He therefore proposes the adaptation of his operation, described in 1902, of end-to-end approximation of the broad ligaments for holding up the pelvic floor after vaginal hysterectomy, to support the replaced uterus. The operation is described in connection with semi-diagrammatic illustrations and its advantages, when employed in hysterectomy, are enumerated. He proposes its utilization to hold the uterus in place, in hopes that it will be found more effective than the superficial operations which, at best, have been unsatisfactory. At least it will be less mutilating than the alternative operation, vaginal hysterectomy. He also refers to his operation of reefing the broad ligaments in the removal of the appendages, also proposed in 1902, and mentions its advantages.

The Diet and Albuminuria.—H. Stern recapitulates the results of a series of experimental studies of eighty-two patients who had albuminuria. The object was to determine the influence of certain types of nutritives and ingesta not on the underlying disease, but on the accompanying symptoms of albuminuria. The substances tested were proteids in the form of milk, eggs, and meats, the commonly employed cabohydrates, and water. Before adding the other proteid-containing ingesta the patients were kept on an exclusive milk diet for two weeks; other proteid materials were then substituted for the milk. The changes observed during the milk diet were diminution of the albumin, in the larger number of cases in which any changes at all occurred, and in a smaller proportion an increase. The influence of rest in diminishing the albuminuria seems marked in these experiments. The change to other proteid diet was more frequently accompanied by a transitory increase than by a decrease, though in the majority no effect was observed. His conclusions as regards carbohydrates and fats are that they have practically little effect on the production of albumin and rise and fall of the albuminuric excretion. The ingestion of large amounts of water, while it enhances diuresis and intestinal peristalsis, and favors gastrointestinal disorders, has little or no effect on the albuminuria in the vast majority of cases. With smaller amounts (up to 35 c.c. per kilogram of body weight daily) there may be slight temporary but not permanent augmentation of the albuminuria. In the treatment of albuminuria *per se* the maximum amount of water taken is of little practical importance unless some advanced heart or kidney trouble, or some gastrointestinal disorder exists; and the minimum amount of water should not for any length of time be less than is required for the intrasystemic osmotic processes.

Psoriasis.—L. Duncan Bulkley concludes that psoriasis is not a purely local disease, but has important constitutional relations. It is not a parasitic disease, in the proper sense of the term; it has no definite microorganism and is not contagious. The immediate skin lesions are probably due to the ordinary microorganisms of the skin becoming pathologic under favoring conditions. It cannot be cured by local treatment, and though this may remove the lesions, they are likely to return. When local treatment appears to cure permanently, the eruption may have been dermatitis seborrhœica, which, in some of its phases, closely resembles psoriasis. Heredity is a relatively unimportant factor, not present in more than one-fourth of the cases and capricious in these. Psoriasis is not a late manifestation of syphilis. It has no one tangible internal cause, but faulty metabolic changes are probably at the bottom of every case, and these may be induced in many ways. The repeated and thorough volumetric analysis of the urine is of great value in guiding the treatment in different cases and at different times. There is no one remedy of universal value in psoriasis, though arsenic is the most generally useful. It can be taken for a long time without harm, if properly given, but it usually is best with other remedies or alternating with them. In acutely developing psoriasis it often acts badly, increasing the eruption. In many cases the proper use of alkalies is of the greatest value. The avoidance of meat or an absolutely vegetable diet is often of great value in treatment, and is sometimes attended with freedom from the eruption. Alcohol must also be avoided. The disorder is an exceedingly rebellious one and prolonged internal treatment—at least two years—is needed. While local treatment is of the greatest value, its temporary success should cause no let up in the general treatment, which sometimes alone relieves the local symptoms. The *x*-ray is a valuable adjunct to local therapeusis, and is sometimes capable of removing chronic lesions by a single application.

Anastomosis of Vessels by the Patching Method.—A. Carrel and C. C. Guthrie describe a method which they have devised for repairing blood-vessels or uniting them to other vessels in the transplantation of organs. The patching consists in closing an opening in the wall

of a vessel by fitting and sewing to its edges a flap taken from another vessel or from some other structure, such as the peritoneum. The anastomosis by this method consists in extirpating a vessel, together with an area or patch from the vessel of origin, the patch being so cut that the mouth of the extirpated vessel is situated in the middle of the patch. The edges of the patch are then fixed to the edges of a similar opening made in the wall of another vessel. The idea is to make the anastomosis in such a way that even in case of slightly imperfect technique resulting in the deposition of fibrin on the lines of suture, the circulation would not be disturbed. They have employed the method in a number of cases of transplantation of kidney and ovary and of simple patching of vessels, in cats and dogs, and though infection often occurred, the circulation in the organs has nearly always been good, and in no case has gangrene of the transplanted organ occurred. If such infection had occurred in an end-to-end or ordinary lateral anastomosis obliteration of the vessel would probably have occurred. The technique is described and fully illustrated. The authors give their conclusions as follows: 1. By the patching method anastomosis of blood-vessels is more safely performed than by the other methods. 2. It prevents the occurrence of gangrene after the transplantation of organs even in case of slight infection. The circulation of a kidney, transplanted with anastomosis of its vessels by the patching method, is good three months after the operation.

The Lancet, November 3, 1906.

Actinomycosis of the Cheek Cured by Iodide of Potassium.—The patient of R. Know was a girl of seven years who came under observation about a month after a swelling had begun to form on the cheek. The trouble had evidently started from inside infection, as abrasions were found on the buccal mucosa caused by two lower molar teeth in a state of advanced caries and with very rough edges. The abscess was opened externally and the pus found to contain the characteristic fungus. The patient was given the iodide in increasing doses until forty-five grains per day were taken. In a month the discharge from the abscess had ceased and her condition was in every way promising. Ten months from the beginning of the treatment she was in good health, the swelling had disappeared, and a firm cicatrix resulted. The author calls attention to the fact that the case shows that infection does not always take place from grain or straw, but may come through food supplies. He notes also that every effort was made to direct the opening of the abscess toward the outside, for fear it might, if allowed to break inside, infect the gastro-intestinal tract.

Infantile Mortality and Goat's Milk.—W. Wright calls attention to the fact that in the countries in which goat's milk is largely relied on as an infant's food, the infant mortality is low. In Italy the infant often nurses directly from the animal. In Norway the milk is placed in a bowl and the child fed therefrom. If the goat is carefully fed there is no odor to the milk. As compared with human milk, that of the goat has more albumin and more casein, and goat's milk shows a lower percentage in these respects than that of the cow. Goat's milk, therefore, more closely approximates human milk than does that of the cow, and for the same reason the curd is less heavy, more floculent, and more easily digested. It is an easy matter to breed the goat when the question is taken up systematically. Finally, the goat is essentially a clean animal. Its feces are practically solid and rolled in balls, thus preventing the possibility of their adhering to the hind quarters. Hence these parts, as also the udders, are always clean. Much of the gross contamination of milk is consequently avoided at the source of supply. The goat is practically immune to tuberculosis, and with but few exceptions the only instances in which this animal has been found suffering from the disease have occurred when they have been housed with tuberculous cows and have obtained their infection therefrom.

So-Called Virulent Syphilis and Its Treatment.—The decline of malignant syphilis has been attributed, says F. J. Lambkin, to first, gradual attenuation of the syphilitic virus; and, second, to improved methods of treatment. Causes which may produce virulent forms of the disease may be poor general physique, living under bad hygiene, malaria, any organic disease, especially renal, alcoholism, and delayed and inefficient treatment. We are in these later days better equipped to treat these cases, as we have methods of introducing mercury into the system which do not upset the digestion and thus deplete the patient. We should always endeavor to ascertain the probable factor in causing the disease in a given case to assume a virulent form and continue in the same groove. We must try to palliate any coexisting disease before we begin specific treatment. The author prefers, under the circumstances named, to give intramuscular injections of metallic mercury in half-grain doses once a week. Sometimes this dose can be halved or quartered. For cases requiring rapid intervention, such as phagedenic chancres, injections of calomel are preferable. Although painful, it is the most soluble mercury salt. Every effort must be made to increase and maintain tissue metabolism. Hot-air baths are a favorite procedure with the author. The patient should take one every second day. Iodide must be given in these virulent cases with circumspection. It should be used intermittently for not more than ten days at a time. For local lesions of the mucous membranes nothing is better than chromic acid and its solutions. To some of the mucous ulcers acid nitrate of mercury is the best application. For phagedenic sores the author uses crude chromic acid under local anesthesia. Its use should be continued until all tissue destruction has disappeared. Charcoal may be used during the separation of the slough and then replaced by iodoform. All large chronic ulcers are to be treated on general surgical principles, rest, cleanliness, opening up all pockets and sinuses, and securing good drainage. For bone lesions we should commence with soothing applications, and if ulceration occurs resort to Volkmann's spoon. Sequestra should be removed early. Ten illustrative cases are appended.

Gastrostaxis.—By this term W. Hale White refers to oozing of blood from the mucous membrane of the stomach. This has been looked on as a vicarious menstruation, but the condition is not confined to the female sex. Many of the cases have been regarded as gastric ulcer. Of the author's twenty-nine patients, all but two were women. The chief symptoms are hematemesis, vomiting apart from the latter, and pain in the region of the stomach. The similarity of these symptoms to those of ulcer is at once apparent, but many of the patients have such symptoms for years, and an autopsy has not revealed any ulcer. The cause of the condition is unknown. Prognosis is good. Differential diagnosis from ulcer is difficult and cannot be positively made unless we have the opportunity of inspecting the gastric mucosa during life or on post mortem. If a patient has not been starved as the result of treatment, the author thinks that with ulcers there is more emaciation. Some cases give a history of chronic dyspepsia, pain after food, and tenderness over the stomach, yet the occurrence of considerable intervals, during which there is no complaint of gastric tenderness, is, perhaps, in favor of gastric oozing. Diagnosis must also include the possibilities of cirrhosis, cardiac disease, and cancer. Treatment must follow along the general lines of the modern cure of cases of ulcer. Epitomized histories are given of the twenty-nine cases above referred to.

British Medical Journal, November 3, 1906.

Huntington's Chorea and Heredity.—In a family coming under the observation of G. S. Mill, the father was a perfectly healthy man, but the mother began to develop symptoms of the disease at the age of thirty, and died at forty-four in great misery. As she died many years ago, the author was, unfortunately, unable to trace the history further back, but she had a brother who suffered from the disease. She had seven children, and of these six were affected as follows: R., now sixty-five, free from the disease, as are also his children and grandchildren. W. (male), disease began at forty, and he died at fifty. A. (female), began at twenty-nine and died at forty; her son, now thirty, suffers from the condition. E. (female), began at thirty and is now forty-two. G. (male), began at twenty-nine and is now forty-nine. C. (male) began at thirty-two and died at forty-four. F. (male), began at thirty and is now forty-five. In all the symptoms have been practically identical. The author states that they commence with a loss of control over the hands. The head is drawn down, and it is with an effort that it is raised, and it wags from side to side. There are slow contractions of the muscles of expression, and the hands and fingers are constantly moving. The gait is

very peculiar, being irregular and spasmodic. The reflexes are much exaggerated. The speech is slow and hesitating. The mind, until nearly the end, is wonderfully clear, and there is great sleeplessness.

Pneumococcic Peritonitis.—The patient of L. E. Ellis was a healthy girl of six years, taken with diarrhea, vomiting, and abdominal pain. On the ninth day of the illness (from the beginning of which signs suggestive of peritonitis had gradually accumulated) a pneumonia was detected. On the eighteenth day of the illness laparotomy was done and yellow-greenish, nonoffensive pus was found in the abdomen. The patient made a good recovery. Examination of the pus showed that it was pneumococcal.

Causes, Sequelæ and Treatment of Pericolic Inflammation.—Details of a series of cases are given by D'Arcy Power. He presents the following conclusions: (1) Pericolitis is not very rare, although it is one of the less common forms of local peritonitis. (2) It occurs in connection with the ascending as well as with the descending colon, but I have seen no case in which it arose in the neighborhood of the transverse colon. (3) The cause of pericolitis may be found within the colon as a result of chronic constipation, in the walls of the colon from ulceration of the mucous membrane, or from the perforation of foreign bodies, outside the colon as a result of injury. (4) Pericolitis ends in resolution, in chronic inflammation, sometimes with extensive thickening of the colon, or in suppuration, which is usually retroperitoneal. (5) The treatment consists in an attempt to prevent the inflammation becoming chronic, and in the early opening of any abscess which may be formed.

Berliner klinische Wochenschrift, October 29, 1906.

A Toxolecithid of Bee Poison.—Morgenroth and Carpi describe experiments made on the properties of the toxin extracted from the poison sacs attached to the stings of honey bees. This, like snake venom and the poison of scorpions, contains a prolecithid having the character of a toxin or amboceptor body which has the property of combining with lecithin to form a specific toxolecithid having marked hemolytic qualities. By adding lecithin to a watery extract of the poison apparatus of bees the hemolytic properties of the latter are greatly increased, and it is possible to produce a body easily soluble in alcohol and salt solution and precipitated by ether, which manifests the characteristic hemolytic power. This substance in distinction to those originally present in the poison presents a marked grade of thermostability. The addition of cholesterin to solutions of this body inhibits the hemolytic action, and when normal horse serum is added to solutions of bee venom plus lecithin the inhibition to the hemolytic power that results depends on the presence of cholesterin in the serum.

A New Reaction for Free Hydrochloric Acid in the Stomach Contents.—Simon proposes the following: A small pinch of pure powdered guaiac resin is dissolved in five c.c. of a mixture composed of ten grains of spirit of nitrous ether and forty grains of alcohol. Several cubic centimeters of this solution, which should be freshly prepared, is layered in a test tube over about five c.c. of the filtered stomach contents. At the line of junction of the two fluids a precipitate of resin at once forms as a grayish ring. If free hydrochloric acid is present this ring in a few seconds becomes distinctly blue, or, if only very small amounts of acid are present, distinctly green. The free hydrochloric acid liberates nitrous acid from the ethylnitrite, and this oxidizes the guaiac resin, thus producing the blue color in the same way as in the well-known test for hemoglobin. Lactic acid in large amounts may give the same reaction, but is never present in sufficient quantities in stomach contents to be a source of error. The author states that the test is just as sensitive as those now in use, notably Günzburg's reaction.

Münchener medizinische Wochenschrift, October 30, 1906.

Observations on the Action of the Roentgen Rays on the Pelvic Organs of Guinea Pigs.—Lengfellner made experiments on guinea pigs to determine the effect of exposure to the Roentgen rays; firstly on the pregnant uterus, and secondly on the ovaries. It was found that exposures of from twenty minutes to an hour made on pregnant animals a few days before term caused either the death of the fetuses or else impaired their vitality to such a degree that they were found barely living when the uterus was opened immediately after killing the animals. It is therefore evident that there is risk in all protracted Roentgen ray exposures of pregnant women, since even if the fetus is not killed it may suffer serious interference with its vital faculties. It was found that the ovaries of both pregnant and nonpregnant guinea pigs also exhibited demonstrable lesions after radiation, and the author further describes an instance in which prolonged amenorrhea was observed in the case of a girl of nineteen years who had been subjected to several exposures in an attempt to secure a satisfactory radiograph of the pelvis.

Deutsche medizinische Wochenschrift, November 1, 1906.

The Diagnosis of Grave Abdominal Contusions.—Schmidt, in discussing this subject, described four cases that came under his observation. Three of these were the result of kicks from horses, and the fourth was caused by a runaway accident. Laparotomy was done in each case, with three recoveries. In analyzing the separate symptoms the author comes to the conclusion that shock, fever, and vomiting are very deceptive signs, since they may be lacking or only slight in even the severest cases. On the other hand, careful and gentle percussion will often reveal dullness due to even small amounts of blood or extravasated fluid, and is always to be regarded as a valuable aid. The greatest importance, however, attaches to the two symptoms of pronounced abdominal tension and tenderness to pressure. If these two symptoms are present to a marked degree and do not subside promptly a serious internal injury must be taken for granted and laparotomy is urgently indicated. The author expresses himself strongly in regard to the use of opium in doubtful cases, severely condemning its administration as long as the diagnosis remains uncertain.

French and Italian Journal

Latent Cancer of the Kidney in a Pregnant Woman, with Congestive and Hemorrhagic Lesions in the Kidney and the Suprarenal Capsule of the Fetus.—René Gaultier reports this case. The patient was a seamstress, thirty-five years old, pregnant seven months. She entered the hospital on account of a cough which was sometimes accompanied by bloody expectoration. The symptoms had begun two or three months before. The dyspnea, which had been slight at first, increased daily, and at the time of entrance caused paroxysms simulating those of asthma. The patient had always been strong and vigorous up to this time. She had had two normal deliveries. The urinary symptoms were negative as far as a renal tumor was concerned. There was neither albumin nor blood. At no time did the patient complain of lumbar pain. The clinical picture was a classic one of a tumor of the mediastinum. The patient died in an attack of dyspnea. Autopsy revealed the presence of a renal cancer. Metastases to the pleura, lungs, and ganglia had given rise to the symptoms. The tumor of the kidney was the size of a hen's egg. It involved the right kidney. Microscopical examination showed it to be an epithelioma. In the kidney and suprarenal capsule of the fetus were noted intense congestion and numerous hemorrhagic foci.—*Annales de Gynécologie et D'Obstétrique, August,* 1906.

Intestinal Origin of Pneumonia in Man and Animals.—A. Calmette, P. Vansteenberghe, and Grysez declare that the pathogeny of the pneumococcic infection of the lung is still very obscure. Up to the present time the attempts to reproduce it experimentally in animals in the laboratory have failed. These investigators used a virulent bacillus which they had isolated from the expectoration of a patient in the second day of pneumonia. The animals experimented upon were the mouse and the guinea-pig. The cultures were introduced by means of an esophageal sound into the stomach of the animals. After twenty-four hours the animals were killed. The lungs were found to be strongly congested and the pulmonary parenchyma contained the pneumococcus in abundance. Some of the cultures had been blackened with smoke, and in such cases the lungs showed masses of carbon. In no case, however, were observed the histological lesions so characteristic of lobar pneumonia in man. These observers next exposed the animals experimented upon to sudden cold. The passage of the microbes into the lung took place, with intense congestion of these organs, but nothing more. These experiments show that raw food which is suspected to be contaminated with pathogenic organisms capable of traversing the intestinal mucosa and of invading the organism, should not be eaten.—*La Presse Médicale,* September 1, 1906.

Book Reviews.

Tuberkulose-Arbeiten aus dem Kaiserlichen Gesundheitsamte. Heft 5. Berlin: Julius Springer, 1906.

This publication is an official description of some of the German sanatoria for tuberculosis, containing plans of buildings, statistics of patients treated, etc. It will be of interest especially to those who have to do with sanatorium management.

Mallattie dell' Orecchio, del Naso, e della Gola. Pel Dott. Tommaso Mancioli. Milano: Ulrico Hoepli, 1907.

This manual, which is of pocket size, covers the general field indicated in its title. It follows along familiar lines and is well illustrated. It will serve a useful purpose for the medical students and practitioners of the country in which it is published.

A Manual of Otology. By Gorham Bacon, M.D., Professor of Otology in Columbia University, New York. Fourth Edition, revised and enlarged, with 134 illustrations and eleven plates. Philadelphia and New York: Lea Brothers & Co., 1906.

This manual has already been favorably noticed in this column. The author's revision has added about forty pages. Among the new topics presented are osteomyelitis, primary jugular bulb, thrombosis, superative inflammation of the labyrinth, etc. The paragraphs relating to leucocytosis, lumbar puncture, and the treatment of facial paralysis have been amplified. The importance of examining pus from aural discharges has led the author to add an appendix on the method of preparing smears, making cultures, and conducting experiment inoculations. Four editions amply testify to the fact that the work has attained its primary purpose as a student's textbook.

La Question Sexuelle; Exposée aux Adultes Cultivés. Par Auguste Forel, Ancien Professeur de Psychiatrie a l'Université de Zurich. Paris: G. Steinheil, 1906.

The subject treated in this volume is of prime importance, and it is here handled in a way that will commend itself to the educated reader. The problem is studied from several points of view, scientific, ethnological, pathological, and social; at the same time the erotic details, found in so many of the books dealing with this subject, are omitted. The first seven chapters are on the natural history and psychology of the sexual life; the eighth chapter deals with the pathology of the subject; and the remainder of the volume discusses the problem from the social side. In this last part are chapters devoted to the relation of the sexual problem to religion, to law, to medicine, to ethics, to politics, to economics, to pedagogy, and to art.

Textbook of Medical Jurisprudence and Toxicology. By John J. Reese, M.D., Late Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; late President of the Medical Jurisprudence Society of Philadelphia. Seventh Edition. Revised by Henry Leffmann, A.M., M.D., Professor of Chemistry and Toxicology in the Woman's Medical College of Pennsylvania; Pathological Chemist to the Jefferson Medical College Hospital. Philadelphia: P. Blakiston's Son & Co., 1906.

The new edition of this well-known book does not differ materially from its predecessors. Such additions and amendments have been made as were necessary to bring it up to date; among the additions being reports of cases of poisoning by potassium chlorate, acetanilid, carbon monoxide boric acid, resorcinol, wormseed, and formaldehyde. It is a good textbook for the student, and is probably the most generally useful and complete of the smaller works dealing with the subjects of medical jurisprudence and toxicology.

Operative Otology, Surgical Pathology and Treatment of Diseases of the Ear. By Clarence J. Blake, M.D., Professor of Otology in Harvard University, and Henry O. Reik, M.D., Associate in Ophthalmology and Otology in Johns Hopkins University. New York and London: D. Appleton & Co., 1906.

This book is designed for all who pay attention to otology, both practitioners and students. It is a record of personal experience rather than a review of literature, discussing in particular the causative conditions of surgically remediable diseases and the surgical measures best applicable to their treatment. Structural descriptions have been limited to those of surgical importance, pathological conditions have been emphasized, and the detail of surgical procedure has been confined to that acceptably applicable to the condition presented. The foregoing statements taken from the preface fairly describe the scope of the work. Coming as it does from two men so well known as are the authors, its pages will command attention. The appearance of the work is unusually attractive. It is well printed on good paper and will undoubtedly find its way to the shelves of every aural surgeon's library. The respective chapter titles are Surgical Anatomy of the Temporal Bone and Adnexa, Aseptic Technique, Diseases of the Auricle and External Auditory Canal, Diseases of the Tympanic Membrane and Tympanum, Possible Complications and Consequences of Suppurative Otitis Media, Middle-Ear Operations, Mastoid Operations and Adventitious Aural Surgery. An appendix is added which treats of various aural matters not included in the foregoing chapters, such as the value of early paracentesis, description of the algesimeter, an instrument for estimating the degree of tenderness over the mastoid, hospital statistics, localizing symptoms of brain abscess, etc.

A Manual of Medical Treatment, or Clinical Therapeutics. By I. Burney Yeo, M.D., F.R.C.P., Emeritus Professor of Medicine King's College, London; Consulting Physician to King's College Hospital, etc. Revised Edition, with Formulæ Adapted to the Standard of Strength of Preparations Employed in America, by Oscar Oldberg, Pharm.D., Dean of the School of Pharmacy, Northwestern University, Member of the Committee of Revision of the Pharmacopœia of the United States. Fourteenth Edition, Twenty-second Thousand, Vol. I., Vol. II. Chicago: W. T. Keener & Co., 1906.

Dr. Yeo's two conveniently-sized volumes comprise what is undoubtedly one of the most practically useful treatises on the management of medical diseases ever put into the hands of practitioners and students. Written in a style charmingly easy yet not discursive, the entire field of practice is covered and the author's funds of experience are drawn upon to furnish telling illustrations and practical points. The present edition, as the title indicates, is intended for use in this country, and the work will no doubt enjoy the same popularity here that it has in Great Britain. In looking through the text one sees much to admire and but little to criticise. Here and there a flaw is discernible, however; for example, in Vol. II., p. 754, in speaking of intravenous infusion, the author states that "the pinch cock is opened and the whole quart is infused in two to four minutes," which is certainly too rapid, while the instruction that the solution is to be "used warm" is a very insufficient direction on the important point of the temperature of the saline fluid. For the most part the work is well abreast of the times and the recent methods have been incorporated, yet under the treatment of leukemia we find no mention of the use of the *x*-ray. Yeo is not a very ardent believer in surgery in the treatment of primarily internal diseases; for example, he deprecates the attempts to reestablish portal circulation by operative means in cirrhosis of the liver, and discredits the value of surgical measures in the treatment of exophthalmic goiter. The prescriptions appended to each chapter are excellent examples of rational therapeutics, and the fact that they are in the earlier sections written without abbreviations should prove helpful to the neophyte. But it would take too much space to catalogue the many excellencies of this most serviceable work, and perhaps the fact that it has required fourteen reprintings in less than that number of years is a more practical index of its value than any tribute from the pen of a reviewer could be.

The Operative Treatment of Prolapse and Retroversion of the Uterus. By J. Inglis Parsons, M.D., M.R.C.P., M.R.C.S., etc. New York: William Wood and Company, 1906.

This little book is a record of the personal experiences of the author in treating these conditions and contains only those procedures which have given him the best results. Some interesting and novel methods of treatment are described, particularly one devised by the author for uterine prolapse. For the purpose of producing a contracting adhesion in the cellular tissues of the broad ligaments he injects a solution of quinine directly into the latter through the vagina by means of a long hypodermic needle. The claims for this operation are brevity, painlessness, no shock or hemorrhage. Until the adhesions have formed the organ must be supported by a cup and stem pessary. In one hundred cases treated in this fashion a recurrence was stated to have occurred in only 5 per cent., and this in very advanced cases. There are a number of other unique procedures described, among them a "constant curette" for retroversion with metrorrhagia, which consists of a pair of electrodes, one being placed in the uterine cavity. It is to be feared that some of the author's suggestions are interesting rather than practical.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-second Annual Meeting, Held at Hot Springs, Ark., November 6, 7, and 8, 1906.

DR. J. HENRY CARSTENS OF DETROIT, PRESIDENT, IN THE CHAIR.

THE scientific work was divided into medical and surgical sections.

Addresses of welcome were delivered by Mayor George R. Belding, in behalf of the City of Hot Springs; by Dr. S. P. Collings, in behalf of the medical profession, and by Hon. Charles G. Greaves.

These addresses were responded to in behalf of the association by Dr. J. M. Mathews of Louisville, Ky.

The Future of the Medical Profession.—Dr. J. HENRY CARSTENS of Detroit, in this, the presidential address, referred to the early history of medicine, and said that great advances had been made during the last thirty-five years. Men of humble origin, but with the right kind of brains, who had an opportunity to enter the profession, had done much to clear up some of the moot questions. By gradually increasing the requirements only the best minds had been able to enter the practice of medicine. Only men with the best mental caliber should be allowed to practice medicine. The second and third-class brains should take up some other calling. Referring to organizations, he said that as the country was large it was desirable to have larger societies in different parts of the country, but that the American Medical Association should not establish a rule and force certain States to join together in the form of a branch; it should be left to the members to organize any kind of way they desired. If a certain branch in the East or the West or the South formed an organization, all right. If they ran over the border into some other branch, what was the difference? We could have a Mississippi Valley Society, a Southern Society, or a New England Society, and still any member of the American Medical Association should have a right to belong to any one or all of them. He was sure that at the next meeting of the American Medical Association this point would be settled. The great men of the medical profession were working unselfishly for the good of the race. The moral tone had been wonderfully elevated. Liars in the medical profession had diminished materially, and with a higher standard he hoped they would soon be eliminated entirely. There were still some liars in the profession, and in his experience there were few among the young members. Some of these liars were of the pious order. They regularly attended church. They were very busy; they could not get there until just when the prayer began; they could only walk half-way down the aisle and stand so that the whole congregation could see them until the prayer was finished. Another of these pious varieties went to church late, walked to the front pew, and dropped down like a bag of flour, with the air of utter exhaustion, the people ever ready to exclaim, "Poor fellow, he works so hard." Another variety of liar was the man who claimed to be a specialist, but who, if he was a surgeon, treated typhoid fever and pneumonia if the patients were wealthy. He would even treat measles and cholera infantum if the grandfather was a millionaire. Physicians were and should be the great teachers of the race; hence they should have broad views of life and a thorough knowledge of all kinds of things. At present they must educate the more intelligent people of the community. But they must themselves be of broad education, and the speaker made an eloquent plea for thorough general knowledge. The days when the medical man only knew something about drugs, or how to treat some diseases, were past. The physician should take an interest in everything that affected the community in which he lived. He should be first and foremost and all the time a physician, but still he should be informed on all kinds of questions. He should thoroughly understand the workings of the inner mind, quickly grasp the weakness and the strength of an individual's mentality, and thus be able to shape the course of the individual and of the community.

Some Mental Symptoms Due to Disease of Nasal Accessory Sinuses.—Dr. J. A. STUCKY of Lexington, Ky., read this paper. (See page 820.)

Typhoid Fever.—Dr. I. H. C. COOK of Hattiesburg, Miss., read a paper on this subject, in which he described the modes of conveyance, and discussed the morbid anatomy, symptomatology, complications, intercurrent diseases, diagnosis, prognosis, and treatment of the disease; likewise the treatment of complications.

Metabolic Aspects of Overfeeding and of Underfeeding.—Dr. Ralph W. W[illegible] of C[illegible] pointed out that by the term overfeeding or forced feeding was meant the giving of an amount of food which furnished the body more energy than it needed, utterly regardless of whether the addition be in the form of proteid, carbohydrate, or fat. The errors in diet, which most of us unfortunately committed, were productive of various disorders as a result of the overtaxing of the digestive, absorptive, assimilative, or excretory organs with excessive products of metabolic activity, and of a series of peculiar derangements pointing to a condition of undernutrition. He referred to the obese, diabetic, and gouty subjects, on the one side, and the neurasthenic, neuralgic, and chlorotic patient, on the other. He treated the subject of overfeeding only as a therapeutic measure and not as a causal factor in disease. Addition of an excess of food, in the form of fat or carbohydrate, exerted, even when given in large amounts, only a slight increase in the energy relations of the system. This applied to an immediate increase in the oxidative processes and not to the later effects of the reserved fat or carbohydrate. Only a part of such excess was burned up in the system, the chief part being stored in the various depositories subject to the checking orders of the system. On the addition of fat to the diet, almost the total excess of energy was turned to the advantage of the body, not in the form of increased energy, but rather in the form of latent energy as a deposition of fat. Zuntz had proven that of 100 grams of fat increase in the diet, 97-98 grams were stored up. With the carbohydrates the relations were not quite so high. A loss of 10 per cent., according to Zuntz, was observed in the total energy available from an increase of carbohydrate. Moreover, the conversion of the carbohydrates into fat was accompanied by some loss of heat. An increase of proteid in the diet raised, on the contrary, the general tissue metabolism, as evidenced by the increased oxidation, far above the normal standards and far above that which could be traced to the activity of the bowel. This primary increase in the oxidative processes, which was effected by a meal rich in proteids, lasted for eight to ten hours. This fact might be expressed more briefly in the statement that every addition of proteid increased the proteid decomposition, the system soon adapting itself to a new equilibrium. It was erroneous to refer every loss of nitrogen to an increased decomposition of body proteid. There was no reason for supposing that tissue proteid was decomposed in any different way than was food proteid. We were not justified in assuming that the products of tissue metabolism were normally or abnormally any different from those of food metabolism under the same conditions. The point of all that was that the increased nitrogen excretion observed under certain conditions might be referable to the proteids of the food and not to those of the tissues. Dr. Webster spoke of proteid-sparing; flesh and fat; increased calorie consumption; increase of nitrogen; indications for forced feeding, and discussed underfeeding. The following general effects of a long-continued underfeeding were to be

recognized: (1) The proteid decomposition sinks up to a certain point, beyond which further decomposition is serious. The body at this point adapts itself to a fairly permanent equilibrium, as is shown by the fact that not so much body proteid is lost in the later periods as in the beginning. Nitrogenous equilibrium can be maintained, as Voit, Rumpf, Siven, and others have shown, on a lower proteid addition than is customary, provided the calorie need is covered. (2) Long-continued underfeeding, aside from very slight degrees of calorie deficit, lead to constant loss, not only of body fat, but also of body proteid, immaterial whether the proteid intake be large or small. The absolute height of the N-excretion depends on the amount of proteid, but the maintenance of nitrogenous equilibrium is independent of the amount as a balance is established to suit the intake. A calorie poor diet, which is rich in proteid, may protect the N-loss or may even raise it for a time, but the final result will be the same as if all parts of the diet were simultaneously reduced. (3) Whenever the addition of food lessens the calorie deficit, a building up of cell material takes place, although the calorie need at this time may not be completely satisfied. This condition lasts until the body is accustomed to the new equilibrium, when N-loss begins anew unless the calorie need is absolutely covered. The author pleaded for a more scientific and more intelligent recognition of the advantages and disadvantages of dietary, bringing about a more normal condition of patients, whether they be racked with disease or suffering with malnutrition, excessive or deficient.

Intestinal Obstruction; with Observations on Its Surgical Treatment.—Dr. H. O. Walker of Detroit, Mich., reported eleven cases of intestinal obstruction in which he had operated since May 16 of this year. Seven of them were chronic, two of which became acute, making practically six acute and five chronic cases of obstruction of the bowel. Six were of the small intestine, five of the large. Two of these cases involved both small and large intestines. The mortality was five, making a percentage of 45.5 per cent., a much better record than was usually obtained, yet he firmly believed that had he seen these cases earlier there would have been little doubt that three of the five who died could have been saved, showing that the great mortality, as Moynihan puts it, was "the mortality of delay." The advantage of early diagnosis and early operation could not be emphasized too strongly. While collapse might be an early symptom of intestinal obstruction, it was not characteristic, but indicated severe peritoneal nerve irritation. Pain was sudden and agonizing in character, which was also an evidence of severe peritoneal irritation, described as colicky with exacerbations, and was persistent until general peritonitis or intestinal gangrene supervened. Vomiting was almost always present at the onset, was incessant and plentiful. The character of vomit was as follows: (1) Stomach contents; (2) bile and mucus; (3) stercoraceous, either with or without fecal odor. Liquid fecal vomit was a late symptom and had a very foul odor, as was observed in case six of internal strangulated hernia at a point in the lower ileum, caused by a back action peristalsis. Abdominal rigidity was not an early symptom in intestinal obstruction such as was found in appendicitis or other localized peritoneal inflammation. Rigidity and tympany were very late symptoms. Peristalsis could be seen occasionally in emaciated subjects with thin abdominal walls where chronic obstruction of the bowel existed.

Dr. T. J. Watkins of Chicago agreed with the essayist as to the importance of early diagnosis and of advocating early operation. His experience led him to believe that early operations for intestinal obstruction were almost certain to result in cures, whereas late operations were almost certain to result fatally. He recalled eight acute cases upon which he had operated in the last two years. Six were operated on within six or twelve hours after obstruction had taken place, and all recovered. The other two were operated on late, and both died.

Dr. Edwin Walker of Evansville, Ind., referred to one cause of delay in operating on cases of intestinal obstruction—the use of cathartics. Cathartics were very much overrated remedies. He had occasion last year to look up the subject, and was impressed with the ignorance of the general profession as to the action of cathartics and the method of prescribing them. In cases of intestinal obstruction cathartics were productive of much harm. In fact, in his judgment there were few intestinal diseases of any kind that were benefited by cathartics.

Dr. F. F. Lawrence of Columbus, O., said the time when the physician should not use cathartics was when intestinal obstruction was suspected. If there was a volvulus, an intussusception, obstruction by bands, he thought cathartics would favor intestinal peristalsis, intestinal perforation, and a funeral. The placing of a patient with intestinal obstruction in the knee-chest or Trendelenburg position, and rectal inflation with air, oil, or water, were equally pernicious.

The subject was further discussed by Drs. A. H. Cordier of Kansas City, Mo.; Channing W. Barrett of Chicago, and J. Henry Carstens of Detroit, all of whom emphasized the importance of making an early diagnosis and of instituting operation at the earliest practicable moment thereafter.

Migraine.—Dr. C. S. Chamberlin of Cincinnati said that after a very careful and fairly extended study of the treatment of migraine, which had included the use of a great number of remedies and combinations of remedies recommended by various writers on the subject, as well as those which his own ingenuity had evoked, he had come to the conclusion that Rachford's plan of treatment was the only one which was not injurious to the patient and which could be depended upon for relief in most cases, and for cure in a considerable ratio of chronic cases. This treatment consisted in the daily administration of the following prescription:

Sodii sulphatis (dry)	30 grains
Sodii salicylatis (from wintergreen)	10 grains
Magnesii sulphatis	50 grains
Lithii benzoatis	5 grains
Tincturæ nucis vomicæ	3 drops
Aquæ destillatæ	ad 4 ounces

This preparation was put up in siphons and charged with carbonic acid. Occasionally Dr. Rachford made some slight variation in the formula, but, as a rule, adhered to that which was here given. As this form of dispensing the prescription was not only very inconvenient, but expensive to a prohibitive degree to most persons, he determined to try it in the form of a granular effervescent salt, and had a quantity manufactured for experimental purposes. He had dispensed fully one hundred pounds of this granular effervescent salt during the last three years, and was convinced that the prescription in this form was fully as efficient as in the more expensive form of a carbonated solution.

The Danger of Dust as a Cause of Tuberculosis.—Dr. George Homan of St. Louis contributed a paper on this subject, in which he submitted the following points: (1) That efforts toward the eradication of human tuberculosis will fail which do not take full account of household dust as a factor in the dissemination of that disease; (2) that scientific tests have shown that the seeds of pulmonary tuberculosis, harbored within doors in the dried state, are capable of retaining their effective vitality for prolonged periods of time; (3) that any method or procedure employed in inhabited buildings which causes dust to be disseminated must be considered as tending to spread the seeds of consumption; (4) that hotels, clubs, theaters, office buildings, schools, churches, and business establishments generally should be required by law to introduce

and operate dustless methods of cleaning. This part of their mechanical equipment should be held as necessary as provisions similarly made for warming, ventilation, and for fire protection and fire escape. The employment of dustless methods in private residences is urged as being equally imperative for the control and suppression of all forms of tuberculous disease.

Retroversio-Flexions in Their Relation to Pregnancy.—Dr. CHANNING W. BARRETT of Chicago said the accompanying diseases of retrodisplacement might cause sterility, but this was by no means constant. What might be expected from those cases in which pregnancy took place or in which retrodisplacement followed pregnancy? There was apt to be an increased displacement, with aggravation of symptoms, and then one of four things might occur: (1) The uterus might return to normal position and the symptoms be relieved or disappear; (2) abortion might and frequently did follow; (3) incarceration might take place, causing abortion, retention of urine, sloughing of portions of the bladder, peritonitis, etc.; (4) pregnancy might continue to term, with the uterus still retroflexed, causing only moderate, mild, or almost no symptoms. This condition might become a complication of labor. The treatment to be advised should be based upon the present conception of the value of different methods of treatment for retrodisplacement; of the danger or absence of danger of radical cure; of the tolerance of pregnant women for an operation; of the value of the life of the child, and, lastly, the method of operation. It must not be based upon a conception of these matters fifteen, ten, or even five years ago. If we could make a laparotomy fairly safe; if this danger was only slightly increased in the pregnant woman; if the rights of the child were recognized, and an operation could be performed which prevented the possibility or probability of a return of the displacement after delivery, then would cases of beginning incarceration or threatened abortion be operated upon early. Last-resort surgery in this as in other conditions would be less popular. The writer called attention to the early replacement of the uterus in cases of retroversion, retroflexion, and the holding of the uterus with a pessary, if necessary; to the value of an anesthetic; to the knee-chest position, etc. In cases of beginning incarceration he condemned the practice of producing abortion in the interests of the child, and likewise condemned the method of puncturing through the posterior cul-de-sac in the interests of the mother, saying that the puncture might be so located as to be equivalent to rupture of the uterus into the peritoneal cavity. In the light of our present-day aseptic technique, the tolerance of pregnant women to operation, and our present methods of permanently curing retrodisplacement without creating new pathology, he entered a plea for more early and efficient treatment of these cases. Ventrosuspensio-fixation was condemned. To operate upon these cases when most advantageous to the mother and child, the operation must offer the following safeguards and advantages: (1) It must be safe for the mother; (2) it must decrease the fetal mortality; (3) it must insure or promise a permanent cure for the retrodisplacement. If these conditions were secured, instead of pregnancy being a bar to an operation, it might at times furnish an urgent argument for an operation. The writer briefly reviewed his method of operating for retrodisplacement as giving the above advantages. Two cases were described illustrating the necessity for operation, one of which was a case of extreme incarceration, and one of early pregnancy manifesting symptoms of abortion in which there were adhesions and an ovarian cyst.

The paper summed up the writer's position in the following conclusions: (1) Retroversio-flexion is a pathological condition worthy of appropriate treatment, operative or nonoperative; (2) pregnancy may be the means of cure of retroversio-flexion, but may, on the other hand, seriously complicate the condition; (3) the retrodisplaced pregnant uterus should be replaced as soon as possible, and, if necessary, held in position by means of a pessary; (4) a retrodisplacement during the early weeks of pregnancy that cannot immediately be replaced should be supervised and efforts made to assist its return to a normal position as growth advances; (5) an irreducible retrodisplaced pregnant uterus that shows beginning signs of intolerance or incarceration should have a radical operation for the retrodisplacement rather than be emptied or punctured; (6) in cases of inevitable abortion, the uterus should be emptied and the retrodisplacement corrected, if possible, the radical operation following later, if necessary; (7) cases of marked incarceration should have the benefit of abdominal section unless abortion is inevitable; (8) cases operated upon should have the radical operation for the retrodisplacement if the conditions are such as to warrant its performance; (9) should a retrodisplacement correct itself, or be corrected during pregnancy without operation, it should be carefully supervised after confinement with a view of permanently correcting the malposition.

Toxemia of Pregnancy.—Dr. D. M. HALL of Memphis reported a case of toxemia of pregnancy, and in reviewing it said there were several unusual features about it. There was a clear history of an attack of uremia with the usual symptoms of edema of the lower extremities, suppression of urine, albuminuria, headache, blindness, and convulsions. Several years later a similar attack occurred during the eighth month of pregnancy, but whether this was uremic or eclamptic was questionable. Later on an attack came on suddenly during the second month of pregnancy. This attack was accompanied by nausea, vomiting, headache, intense aching and restlessness, suppression of urine, albuminuria, diminution of urea, and acute splenitis, but no edema, blindness, or convulsions. During the eighth month of this pregnancy there was a sudden attack of nausea, attended by vomiting, intense aching and restlessness, pain and tenderness over the liver, lessened quantity of urea and urine, but no splenitis, headache, blindness, albuminuria, or convulsions.

Blunt Dissection in Plastic Gynecological Operations.—Dr. T. J. WATKINS of Chicago said the advantages usually claimed for blunt dissection with scissors over the method heretofore in use of denuding in strips were, *first*, that very much time was saved; *second*, raw surfaces were made which would give firmer union. The operator got down into muscular and connective tissue much better than by denudation; *third*, there was less hemorrhage.

Pubiotomy and Its Relative Indications.—Dr. E. B. MONTGOMERY of Quincy, Ill., said that his interest in this operation had its beginning from the fact that he was obliged to do it in 1903 to enable him to deliver a child which was impacted in the pelvis in a mentoposterior position. Examination of the literature of the subject showed him that no such procedure had ever been resorted to in this country for such a condition, nor had a lateral section of the pubis for any condition before been made on this side of the Atlantic. Satisfied with the outcome in this case, he began a thorough investigation of the literature of the operation of Gigli, and presented this in a paper before the Obstetrical Section of the Fifteenth International Medical Congress, held in Lisbon, in April of this year. The results in the 134 cases collected by him from thirty-five different operators were uniformly favorable, in that there were no deaths in cases not previously infected, and all patients recovered with perfect union of the bone and with perfect gait. An indication other than contracted pelvis for the performance of pubiotomy was the occurrence of an impacted mentoposterior face presentation in which a change of position could not be affected by the usual procedures. In the case reported by the essayist a lateral section of the pubis was done, and labor terminated by delivery of a living child with forceps. The mother made an excellent recovery.

Operative Work for Hypertrophied Prostate.—Drs. Bransford Lewis and C. E. Burford of St. Louis contributed a joint paper on this subject, cited illustrative cases, and exhibited a number of interesting specimens. They presented the following conclusions: (1) Prostatic cases, if correctly estimated and judiciously treated, are now among the most satisfactory that seek the aid of the surgeon; (2) diagnosis, both accurate and comprehensive, is essential to the attainment of such success and satisfaction; (3) not all cases of enlarged prostate produce obstruction; (4) not all cases, even though producing obstruction, require operation; (5) not all cases that are producing obstruction and do require operation demand the same operation; (6) not all cases of prostatic obstruction are produced by enlargement or outgrowth; some are produced by definite contraction of the vesical neck, no hypertrophy being present. It is impossible to determine such conditions by palpating per rectum only; (7) the retrograde cystoscope is the most serviceable aid attainable in determining these questions, in respective cases, hence its value in this work is inestimable; (8) experience proves that neither advanced age, depression of health, nor disease of the heart or kidneys debars the patient from the hope of operative relief. Operation reclaims many, even after they have suffered uremic attack; (9) the longer required operative measures are postponed the greater the likelihood of establishing spreading infections and renal involvement, conditions much less amenable to surgical relief than simple obstruction at the vesical neck; (10) three weeks should be sufficient to demonstrate how much may be expected from palliative treatment, after which any operative treatment necessary should be carried out as soon as possible. Delays are dangerous.

Clinical Psychology.—Dr. Frank Parsons Norbury of Jacksonville, Ill., delivered this, the address in medicine. In all ages, he said, man had sought to solve the mysteries of his own ruling mind. The researches of to-day had translated the science of mind from terms of the metaphysician with its confusing verbiage to words that signified something by defining the facts of physiological psychology, psychophysics, and clinical psychology. Mind to-day was studied from the basis of the general law laid down by James, namely, that no mental modification ever occurred which was not accompanied or followed by a bodily change. The brain itself did not act (it is a passive organ), but reacted to stimuli through the peripheral sense organs, thus creating a reflex either in the sensory, motor, or higher psychical cells. Psychology endeavored to study these reactions. Herbert Spencer, in his "Synthetical Psychology," laid the foundation for these studies both normal and morbid. Drs. Hughlings Jackson, Charcot, Mercier, Janet, Wundt, Maudsley, Wernicke, Kräpelin, and others had applied these principles to clinical medicine. Speculative psychology had no place in the modern new psychology. Physiological psychology, aided by the coordinate science of physics, had overcome the dissatisfaction growing out of introspective psychology. It had raised the physiological unit, as stated by Mercier, namely, "That a nervous process which, when transmitted to muscles, issues in a movement, and is accompanied by a mental state," to the highest power, as shown in conduct. Conduct was the criterion of soundness or unsoundness of mind. It was the product of innate character; of environment, of experience, and numerous other modifying conditions.

Refined methods of analysis applied in the study of sensation, of perception, of memory, of thought, of feeling, and of the disorders of the will revealed mind in its constitution. In analytical study it was necessary to note negative as well as positive results. These methods applied to the borderline anomalous mental states, viz., the neurasthenic, the psychosthenic, the hysteric, the epileptic, enabled us to define their full clinical significance. We should follow the clinical methods of Janet in studying these very varied mental anomalies. A clinical résumé of these states was given, emphasizing Janet's dictum, that we must know well the patient, his life, his education, his disposition, his ideas. We must study his acts, his words, written and spoken, in formulating a basis for diagnosis. Heredity was not considered in these studies with the same degree of insistence as that advocated by Morel.

Therapeutic methods resolved themselves into the personality of the physician, his consideration, patience, and earnestness; his ability to take a broad educational view of the whole subject and apply wholesome, helpful methods both in the physical and mental considerations. In no place in our therapeutic art did we find a greater call for the highest application of educational means and methods than in the treatment of nervous disorders, as found in the psychoneuroses. The educational growth of character was imperative. Moral education preceded mastership in every act, because the training which mastery involved reacted upon character, gave it steadiness and solidity. Educational methods alone would not give the results; we must build up, overcome the fatigue bodily, intellectual, and emotional. This required fat and blood, strength and equipoise. The connection between sane living and sound work was a psychological and physiological necessity.

Surgical Principles and Theories.—Dr. F. F. Lawrence of Columbus, O., delivered this, the address on surgery. He said that surgery was either an art founded upon exact science, or it was a gigantic fake founded upon empiricism. Every science was and must be founded upon principles which were as enduring as truth. Every principle, every truth must be preceded by theory, which was only another word for ideal. To make our theories or ideals conform to truth, and exemplify a scientific proposition, was to convert that theory or ideal into a fact. To sacrifice on the altar of personal vanity or ambition one jot or tittle of truth or science was to sacrifice the entire principle. Empiricism had been the foundation of quackery from the earliest days, and to encourage, practise, or teach any of our surgical methods empirically was to justify and father quackery. It was unreasonable, therefore, to expect that any man could put into practice a scientific principle if he knew not a thing about any of those sciences upon which surgery rested, namely, philosophy, anatomy, physiology, pathology, psychology, embryology, and biology, together with those collateral branches, chemistry, histology, bacteriology, and therapeutics.

The human body should be viewed as a machine. Its surgical or medical repair should be based upon the idea of the province of a thorough mechanism. There was no part of the body which was not constructed on a true philosophy, and its repair required a knowledge of natural philosophy. All the other ologies and osophies were useful only in determining the need and character of repair, hence any surgical effort not philosophical was unsurgical. Teaching of the principles upon which the treatment of a surgical case was based should be the most attractive as well as the most important part of the physician's efforts. To accomplish this methods of teaching and practice should be consistent, and both could be revised with benefit. Traumatism should be given the consideration due its importance as a factor in infection. Fads and fancies should not command the respect of the profession, and nonessentials should not be given prominence in teachings. Surgery should be taught as an art which rested upon exact or scientific principles, hence one in which philosophy was equally important with pathology, and anatomy of greater import than the microscope, although the latter was a necessary adjunct. A man might be a good physician but a poor surgeon. The converse, however, was not true, for a man could not be a surgeon who was not a good physician; hence a special qualification might be advantageous. Hospital construction and hospital management should be consistent with the teachings of hygiene, segre-

gation of patients, isolation of infected cases, space per bed, and all minor details should be worked out by men trained in sanitary science instead of by architects and other laymen. Endowments for the working out and proving surgical principles and honors to the workers might be worthy of serious consideration. The one great principle, that a surgical condition was always surgical, should be constantly emphasized to the end that *dernier resort* operations might cease to be the bane of the profession and the boon of the undertaker.

Present Operative Necessities for Cure in Tuberculous Orchitis.—Dr. Charles E. Bennett of Fort Wayne, Ind., in summing up, said: (1) To be sure of a cure, all that is infected with tuberculosis must be removed; (2) primary invasion statistics are so variable that the operator should consider his testicular tuberculosis as primary unless other foci are found that disprove the supposition; (3) the modes of infection are so many that the surgeon should be on his guard constantly. This is especially true in infection during the act of cohabitation; (4) the desexation bugbear should be entirely removed from the patient's mind, and instead hope should be given him for a continuation of his copulative power; (5) injections of paraffin in producing artificial testes are good from a cosmetic standpoint, and good also from the great satisfaction they give the patient. It is entirely devoid of danger when properly done; (6) operations, when indicated, should be immediate, followed by prophylactic and hygienic treatment until the maximum improvement is gained.

The author gave the operative technique used by him in double orchovasectomy, and showed how comparatively easy it was to extract the vas deferens from along its course even down to the ejaculatory duct region. He reported two cases to illustrate the postoperative benefit gained. One of them was injected with paraffin, according to the Gersuny method of small quantities at a time, with frequent sittings. The artificial testes were, from the standpoint of size, location and permanency, all that could be desired.

Head Injuries.—Dr. William Britt Burns of Memphis reported three cases of head injuries which had a bearing especially on injuries of the middle meningeal artery.

Nonlithogenous Obstruction of Biliary Ducts.—Dr. A. H. Cordier of Kansas City, Mo., said that for years gallstones were the only condition that received much attention from the pathologist and surgeon. Further clinical study, operative and post-mortem findings, had demonstrated beyond doubt that gallstones were the result of a preexisting disease of the ducts and gall-bladder, and that in the great majority of instances this disease was of bacterial origin. It was claimed that those of sedentary habits, and insane patients were especially prone to the formation of gallstones, and that at post-mortems a large number of gallstones were often found in patients who had died of other diseases, and who during life had not manifested any symptoms of gallstones. This latter statement was used by some even to-day as an argument against the surgical management of these cases. Gallstones did not form in a few days; they were late manifestations of a preexisting disease. The gallstone cases with which the profession was familiar presented typical histories. The author spoke of stricture of the common duct, saying that it might have its origin in the long incarceration of a stone, the stone later passing into the duodenum or ulcerating into the bowel. In that event no stone would be found at the time of operating. Numerous instances of this kind had been reported. Drainage of the gall-bladder externally would become less and less a procedure resorted to as surgeons appreciated more that the gall-bladder, like the appendix, when full of strictures, was best taken care of in a specimen bottle filled with a good preservative.

There was a class of cases presenting an obscure train of symptoms pointing to the vicinity of gall-bladder and biliary ducts as their source. For instance, a vague sense of uneasiness; occasionally painful spells lasting a few minutes, with attacks of indigestion and painful flatulency. At the operation no stones were found; no stricture of the ducts was discovered; no visible changes in the gall-bladder were discernible; in fact, nothing was detected except a few adhesions between the cystic duct and common duct or duodenum. A separation of these adhesions, with a liberation of the bound-down ducts and viscus from the constantly nagging, distended stomach and intestines, would, as a rule, bring relief to the patient. If an obstruction was located in the cystic duct, and the gall-bladder escaped, the usual contraction due to the presence of a cholecystitis, this viscus might continue to manufacture mucus, and if infected, as it usually was, a mucopurulent distention took place, and a pyriform retention cyst was produced, usually detectable below the border of the liver in emaciated patients. In this condition jaundice was absent, and the patient would have fever and stomach and intestinal digestive disturbances. These cases were especially liable to recurring attacks of fever, as the absence of bile in the gall-bladder robbed nature of one of the most efficient inhibiting bactericidal fluids. These were fit cases for a cholecystectomy, as drainage of the gall-bladder was too uncertain in its curative effects, the opening either refusing to close, or if it did close, the symptoms were renewed.

When the complete obstruction of the duct was the outcome of a long impacted stone resulting in a cancer, the diagnosis of the latter was extremely difficult before operation. Cancerous obstruction occurred most frequently in the lower portion of the common duct. This was likewise the location of most lithogenous obstructions. In determining the existence of an obstruction, its location, extent, character, and time of operating, he had for fourteen years resorted to hydrostatic pressure, by introducing through an aspirating needle into the gall-bladder a saline solution from a moderate height, or if this viscus had been opened, the nozzle of an irrigating syringe, or if the common duct had been opened, by irrigating directly into the duct. In cases in which the duct was embedded in a mass of adhesions and had lost its identity, it could be made to stand out distinctly by water pressure introduced through the gall-bladder, provided the cystic duct was patent. By this same process the patency of the duct, after removal of one or more stones, could be determined, as he had on several occasions run rather a large quantity of saline solution directly into the duodenum through the gall-bladder, cystic and common ducts. As a means of determining the security of the duct stitching, where the opening in this canal was closed by suture, this method was invaluable, as disappearing stones and other débris could thus be washed out of the biliary tract.

The following papers were read and discussed: "Gallstones, Report of Two Cases," by Dr. J. H. Barnett of Pikeville, Tenn.; "Pruritus of the Anal Region," by Dr. Bernard Asman of Louisville, Ky.; "Diagnosis and Treatment of Brain Traumatism," by Dr. John N. Sluss of Indianapolis, Ind.; "Asthma with Mixed Infection Following Repeated Attacks of La Grippe," by Dr. William F. Waugh of Chicago; "Some Medical Notes on Frontal Sinusitis," by Dr. A. E. Prince of Springfield, Ill.; "The True Cause of Functional Neuroses," by Dr. G. G. Buford of Memphis, Tenn.; "A Possible Explanation of the Formation of Drug Habits," by Dr. H. A. Rodebaugh of Columbus, O.; "Specific Treatment of Tuberculosis Pulmonalis," by Dr. E. G. Epler of Fort Smith, Ark.; "Report of Cases of Probable Maternal Impressions," by Dr. J. Madison Walton of Memphis, Tenn.; "Some Clinical Observations in Tuberculosis," by Dr. William Porter of St. Louis, Mo.; "Eye Findings in Arteriosclerosis," by Dr. George F. Suker of Chicago; "Remarks on Combined Degeneration of the Spinal Cord," by Dr. Hugh T. Patrick of Chicago; "The

Entoning of the Psychic Neurons in Neurotherapy and in General Therapeutics," by Dr. C. H. Hughes of St. Louis, Mo.; "Yellow Fever and Mosquitos in New Orleans in 1905," by Dr. Quitman Kohnke of New Orleans, La.; "Operations for Pyothorax," by Dr. Spencer Graves of St. Louis, Mo.; "What to do in the Presence of Obscure and Persistent Abdominal Symptoms," by Dr. H. H. Grant of Louisville, Ky.; "Etiology, Pathology, and Operative Treatment of Deformities of the Face and Mouth due to Malrelations of the Face and Jaws," by Dr. V. P. Blair of St. Louis, Mo.; "Successful Obliteration of Hemangioma Cavernosum of the Upper Lip," by Dr. Francis Reder of St. Louis, Mo.

Drs. Martin F. Engman and W. H. Mook of St. Louis, Mo., gave lantern slide demonstrations of the *Spirochæta pallida* in various syphilitic lesions.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. H. H. Grant of Louisville, Ky.; *Vice-Presidents,* Dr. Barr of Hot Springs, Ark., and Dr. T. C. Witherspoon of St. Louis, Mo.; *Secretary,* Dr. Henry Enos Tuley of Louisville, Ky., reelected; *Treasurer,* Dr. Samuel C. Stanton of Chicago, Ill., reelected.

Columbus, O., was selected as the place for holding the next annual meeting; time, October, 1907.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 5, 1906.

DR. SAMUEL LLOYD IN THE CHAIR.

A Case of Laryngectomy.—Dr. HOWARD LILIENTHAL presented a man, aged about fifty years, on whom he had performed laryngectomy for carcinoma. The larynx was removed last February and in two stages, doing first a preliminary tracheotomy and, one week later, a laryngectomy. The specimen was presented. The man gained forty pounds in weight and to-day was perfectly well. Of course the man could not phonate, but he could make himself understood by using the muscles of the mouth. The operation of laryngectomy was not so formidable now as formerly. The patient had not one single sign of recurrence.

A Case of Cancer of the Tongue.—Dr. ROBERT H. M. DAWBARN presented a man, sixty-three years old, upon whom he had operated January 29 last, removing the entire tongue, barring 1 cm. of the hyoid attachment. The right tonsil and a mass of diseased submaxillary lymph nodes were also extirpated. Both submaxillary and sublingual glands were removed. The Kocher incision was used. Compresses wrung out of boiling water were applied to the freshly cut surface. The wound was best not sewn at all, and it was useless to introduce packing, for it would soon become soaked with saliva. Instead, a fountain syringe full of 1-10,000. potassium permanganate solution hung at the head of the bed, and hourly a stream was run into the mouth and out of the wound. After emphasizing the danger of inhalation pneumonia, he said that could be avoided by having the head lower than the chest, as by elevating the foot of the bed. This postural position should be retained until the patient could swallow ice water without coughing.

Case of Esophageal Stricture.—Dr. WILLY MEYER presented a young man, eighteen years old, who came under his observation two and a half years ago with an absolute stricture of the esophagus, caused by caustic lye when he was a child of five years. For eight years he had introduced food through a gastric fistula. All attempts to enter the stomach from above had failed. An osteoplastic flap was made of "U"-shape, and it was found that the esophagus was entirely obliterated for some distance. One of the most interesting features in this case was that the boy had increased in weight during the past ten years. He chewed his food and then blew it into his stomach through a water-tight fistula. The lad learned to do this in a very clever way and ate the same food as did other members of his family.

Brain and Skull Surgery Made Safer by Sequestration-Anemia; with Five Recent Illustrative Operations. Dr. ROBERT H. M. DAWBARN read this paper. He said that experience had shown that one could with safety withdraw into the limbs some quarts of the whole bulk of blood, which constituted one-thirteenth of the body weight. One could sequestrate before operation and retain in the limbs by cordage enough blood to make a striking difference in loss of blood from the operative field. This temporary bleeding into the patient's own extremities was controlled as to degree by the finger upon the pulse. Its original volume and force being estimated, the sequestration proceeded until there was plainly noticeable softening and lessening of tension, and, at this point, the operation should begin. A towel folded lengthwise was wrapped about each thigh close to the trunk, and upon this a rubber tube was tightened. This should stop the venous but not the arterial current. After from five to ten minutes the softened pulse would indicate time to begin operation. No case had ever been recorded in which stagnation of blood within a limb for a period as short as half an hour had been followed by gangrene; but for safety, after fifteen minutes the assistant should begin to cord the remaining two limbs, and almost at the same time commence to release those first constricted. In long operations this shifting from arms to thighs and back again had been done repeatedly. But, as a rule, only in case the limbs grew excessively swollen, or the pulse demanded a change, was the tension altered during the operation. In a few plethoric individuals he had used constriction on all four extremities at once. After this practice, but before releasing the tourniquet, the blood in every divided vessel should be firmly clotted by the application of gauze sponges wrung out of actually boiling water. No one need fear ill results of this procedure on even the most delicate tissues. To avoid blistering, one should avoid contact with mucous membrane or skin. Dr. Dawbarn gave the following advantages of the method by sequestration in brain surgery: (1) A striking diminution of the amount of anesthetic needed, with consequent relative safeguard against bleeding due to straining from subsequent vomiting, and against hernia cerebri, and also against lowering of vital heat; (2) ease of control of hemorrhage during operation, because of lessened intravascular tension; (3) a shortened operation, because of a dry field; (4) through lowered intracranial pressure consequent upon accumulation of blood elsewhere, there was lessened danger of sudden death from pressure upon the respiratory center during work upon brain tumor, or upon depressed fractures, etc., and indeed, just in proportion as there was bleeding, whether external or into the limbs, there was increased depth and frequency of breathing, which, by oxygenating the blood, helped to prevent shock; (5) more space between brain and brain case, enabling the operator to work between, in removing old clots requiring curettage, or the separation of adhesions, etc., without risk of lacerating the brain surface. Dr. Dawbarn concluded his paper with the recital of four interesting cases.

Dr. JOHN A. WYETH said that constricting an extremity for the purpose of holding the blood volume was an old practice, and used by surgeons from time immemorial for the arrest or retardation of internal hemorrhage. Such successful results had been obtained that he wondered that it had not been thought of before in surgery of the skull and brain. He advised doing many of these operations in two sittings. In view of the danger of coagulation of blood in the veins, he suggested that they be not completely constricted, not to apply the band so tightly that the blood pumped from the arteries into the veins would not be delivered. He also advised alternating from one arm or one leg to the other. With regard to the necessity for cerebral

anemia prior to operations, he called attention to Dr. Senn's heroic method of isolating the trachea and then constricting the entire neck. Dr. Wyeth thought this to be a little too heroic. A temporary ligature could be passed around the carotid artery without injuring it.

Dr. WILLY MEYER called attention to Bier's treatment by passive congestion, a ligature in some instances being applied to the lower extremity and left on during the entire night without any trouble arising from it. In healthy vessels fear of injury from these constrictions was unfounded, if not applied too long.

Dr. Dawbarn closed the discussion.

Remarks on the Osteoplastic Resection of the Costal Arch, in Order to Reach Vault of the Diaphragm.—Dr. WILLY MEYER read this paper, which was read before the Section on Surgery and Anatomy of the American Medical Association, at the fifty-seventh annual session, June, 1906. Two cases were related which proved the great help one might expect from the osteoplastic raising of the lower part of the thorax, when it became necessary to reach ordinarily inaccessible organs within the phrenic concavity. He said that the cases in which this osteoplastic operation would prove to be especially useful were those of injury to the liver and spleen (stab and bullet wounds, as well as lacerations, due to a blunt force), also injuries and diseases of the diaphragm (hernia), and of the cardiac end of the stomach. Inflammatory troubles (liver abscess and subphrenic abscess) would be attacked to better advantage through or just beneath the complemental space of the pleural cavity after resection of one or more ribs.

Tumors of the Larynx, with Reports of Two Laryngectomies, One Hemilaryngectomy, and Three Thyrotomies.—Dr. JOHN F. ERDMANN presented this paper, which was read by title.

Presentation of a Gas-Ether Inhaler.—Dr. VICTOR COX PEDERSEN presented this apparatus.

Specimen of Tumor of Larynx.—Dr. ERDMANN presented this specimen, which was to illustrate one of the cases reported in his paper.

Specimen of Intraligamentous Cyst.—Dr. ERDMANN presented this specimen, which was removed from a woman, forty-four years old, and from her left side. This was the second one he had removed from the left side this year.

Specimen of Fibroid Arising from the Uterus.—Dr. SAMUEL LLOYD presented this specimen, which he removed from a woman who was not five feet tall, and whose abdomen was as large as she was tall. She had had this tumor for two years, and had been tapped, with the idea that she had ascites. There was a large quantity of ascitic fluid present. There was nothing of especial interest beyond the enormous size of the growth. A supravaginal hysterectomy was performed.

Dr. EDWARD W. PETERSEN was elected secretary of the Section, the former secretary, Dr. Warren S. Bickham, having removed to New Orleans.

COLLEGE OF PHYSICIANS OF PHILADELPHIA: SECTION ON GENERAL MEDICINE.

AT a stated meeting held October 8, Dr. J. DUTTON STEELE presented a communication entitled, "The Muscle-nucleus Test in Pancreatic Disease." It had been claimed that in the total absence of the pancreas or in occlusion of the pancreatic duct, the nuclei in bits of muscle introduced into the stomach were unaffected by the digestive process, while such nuclei were destroyed in the presence of the secretion of the gland in the intestinal tract. Clinical and experimental observations made by Dr. Steele, however, failed to substantiate these claims, inasmuch as the nuclei were found to persist in some cases in which the duct was occluded or the pancreas diseased, and they were lost in other instances in which these conditions did not exist. Dr. HENRY D. JUMP read a paper entitled "A Case of Typhoid Fever with Unusual Enlargement of the Spleen." The disease set in with a chill, the spleen extended from the seventh intercostal space to three fingers' breadth below the costal margin, the temperature became elevated, a few rose spots appeared, the Gruber-Widal test yielded positive results, and typhoid bacilli were found in the urine. The red blood-cell count was remarkably low (less than 2,000,000), as was also the hemoglobin percentage (50 per cent.), but there was no leukocytosis, and malarial plasmodia could not be found in the blood. Dr. FREDERICK FRALEY read a communication entitled "A Study of Five Hundred Cases of Pleurisy Occurring in the Pennsylvania Hospital." The paper represented an elaborate analysis of the cases that came under observation during a period of ten years, and dealt with etiology, symptomatology, diagnosis, complications, and treatment. Drs. JOSEPH SAILER and CLIFFORD B. FARR presented a communication entitled "Methods of Altering the Secretion of Pepsin." They found, among other things, that administration of moderate doses of dilute hydrochloric acid before meals proved extremely serviceable under various conditions of deficient peptic digestion. Dr. HERMAN B. ALLYN presented a communication entitled "The Treatment of Acute Gastritis." The important indications are to empty the gastrointestinal tract and place the stomach at rest. Dr. JUDSON DALAND read a paper entitled "Some Clinical Aspects of Indicanuria." He pointed out that indican is a decomposition product, representing the action of bacteria on animal proteid in the intestine, and he recited the various conditions in which this substance is present in the urine in larger than the normal physiological amounts.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

L'ATAXIE TABETIQUE, SES ORIGINES, SON TRAITEMENT PAR LA REEDUCATION DES MOUVEMENTS. Par le Dr. H. S. FRENKEL. 8vo, 327 pages, illustrated, paper. Felix Alcan, Editeur, Paris.

LA RÉGÉNERATION DES FAMILLES ET RACES TARÉES. Dr. E. CONTET. 12mo, 176 pages, paper. Vigot Frères, Editeurs, Paris.

L'ÉVALUATION DES INCAPACITÉS PERMANENTES. Par le Dr. CH. REMY. 12mo, 250 pages, flexible muslin, illustrated. Vigot Frères, Editeurs, Paris.

RECENT ADVANCES IN THE PHYSIOLOGY OF DIGESTION. By ERNEST H. STARLING, M.D., F.R.S. 8vo, 156 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $2.00.

TEXTBOOK OF MIDWIFERY FOR NURSES. By ROBERT JARDINE, M.D., Edin., M.R.C.S., Eng., F.F.P. and S., Glasg., F.R.S., Edin. 12mo, third edition, 276 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $1.50.

ESSENTIALS OF HUMAN PHYSIOLOGY. By D. NOEL PATON, M.D., B.Sc., F.R.C.P. Ed. Second edition, revised and enlarged. 8vo, 444 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $2.75.

DIET IN HEALTH AND DISEASE. By JULIUS FRIEDENWALD, M.D., and JOHN RUHRAH, M.D. Second edition, thoroughly revised and enlarged. 8vo, 728 pages, muslin. W. B. Saunders Company, Philadelphia. Price, $4.00.

PREVALENT DISEASES OF THE EYE. By SAMUEL THEOBALD, M.D. 8vo, 551 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $4.50.

SYPHILIS DU POUMON. Par le Dr. BERIEL. 8vo, 346 pages, illustrated, paper. G. Steinheil, Editeur, Paris.

GUIDE PRATIQUE POUR LE CHOIX DES LUNETTES. Par le Dr. A. TROUSSEAU. 16mo, 102 pages, muslin. F. R. De Rudeval, Editeur, Paris.

RETINOSCOPY (OR SHADOW TEST). By JAMES THORINGTON, A.M., M.D. Fifth edition, revised and enlarged. 8vo, 67 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.00.

ATLAS AND TEXTBOOK OF HUMAN ANATOMY. By Dr. JOHANNES SOBOTTA. Edited with additions by J. PLAYFAIR MCMURRICH, A.M., Ph.D. Volume I. 8vo, 258 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $6.00.

PHOTOSCOPY (SKIASCOPY OR RETINOSCOPY). By MARK D. STEVENSON, M.D. 8vo, 126 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $1.25.

SAUNDERS' POCKET MEDICAL FORMULARY. By WILLIAM M. POWELL, M.D. Eighth edition, thoroughly revised, enlarged, and adapted to the eighth revision (1905) of the U. S. Pharmacopœia. 16mo, 298 pages, flexible leather. W. B. Saunders Company, Philadelphia. Price, $1.75.

OBSTETRICS FOR NURSES. By JOSEPH B. DE LEE, A.M., M.D. Second edition, thoroughly revised and enlarged. 8vo, illustrated, 510 pages, muslin. W. B. Saunders Company, Philadelphia. Price, $2.50.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. By W. A. NEWMAN DORLAND, A.M., M.D. Fourth edition, revised and enlarged. 8vo, 836 pages, illustrated, flexible morocco. W. B. Saunders Company, Philadelphia. Price, $4.50.

TEXTBOOK OF COMPARATIVE GENERAL PATHOLOGY. By Professor Dr. TH. KITT of Munich. 8vo, 307 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $5.25.

OPERATIONS UPON THE INTESTINES AND STOMACH. By ALFRED H. GOULD, M.D. 4to, 302 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $5.00.

ATLAS OF CUTANEOUS MORBID HISTOLOGY. By Dr. MAX JOSEPH and J. B. VAN DEVENTER. 4to, illustrated, 48 pages, muslin. W. T. Keener & Co., Chicago. $5.00.

ESSENTIALS OF MEDICAL ELECTRICITY. By EDWARD REGINALD MORTON, M.D., C.M. 12mo, 192 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $1.50.

A TEXTBOOK OF OBSTETRICS. By BARTON COOKE HIRST, M.D. Fifth edition, revised and enlarged. 8vo, 915 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $5.00.

ABDOMINAL OPERATIONS. By B. G. A. MOYNIHAN, M.S. (London), F.R.C.S. Second edition, thoroughly revised. 8vo, 815 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $7.00.

PRACTICE OF GYNECOLOGY. By WILLIAM EASTERLY ASHTON, M.D., LL.D. Third edition, revised and enlarged. 8vo, 1,097 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $6.50.

A SYLLABUS OF MATERIA MEDICA. By WARREN COLEMAN, M.D. Third edition, revised to conform to the Eighth Decennial Revision of the U. S. Pharmacopœia. 32mo, 186 pages, muslin. William Wood and Company, New York City. Price, $1.00.

TABES DORSALIS, By DAVID FERRIER, M.D., LL.D., F.R.S. 8vo, 132 pages, illustrated, muslin. William Wood and Company, New York City. Price, $1.50.

DISEASES OF THE STOMACH. By MAX EINHORN, M.D. Fourth revised edition. 8vo, 559 pages, illustrated, muslin. William Wood and Company, New York City. Price, $3.50.

DIE TUBERCULOSE DER MENSCHLICHEN GELENKE SOWIE DER BRUSTWAND UND DES SCHADELS. By Professor Dr. FRANZ KÖNIG, Berlin. 8vo, 166 pages, illustrated, paper. Verlag von August Hirschwald, Berlin.

A PRIMER OF PSYCHOLOGY AND MENTAL DISEASE. By C. B. BURR, M.D. Third Edition, thoroughly revised. 12mo, 183 pages, illustrated, muslin. F. A. Davis Company, Philadelphia. Price, $1.25.

STUDIES IN THE PSYCHOLOGY OF SEX. By HAVELOCK ELLIS. 8vo, 285 pages, muslin. F. A. Davis Company, Philadelphia. Price, $2.00.

MOTOR APPARATUS OF THE EYES. By GEORGE T. STEVENS, M.D., Ph.D. 8vo, 488 pages, illustrated, muslin. F. A. Davis Company, Philadelphia. Price, $4.50.

THE EAR AND ITS DISEASES. By SETH SCOTT BISHOP, B.S., M.D., LL.D. 8vo, 439 pages, illustrated, muslin. F. A. Davis Company, Philadelphia. Price, $4.00.

TRAITÉ DES MALADIES DU NEZ. By Dr. A. MENIER. 16mo, 661 pages, illustrated, muslin. A. Maloine, Editeur, Paris. Price, 12 fr.

BUFF, A TALE FOR THE THOUGHTFUL. By a Physiopath. 16mo, 255 pages, muslin. Little, Brown & Co., Boston. Price, $1.00.

A TEXTBOOK OF ELEMENTARY ANALYTICAL CHEMISTRY, QUALITATIVE AND VOLUMETRIC. By JOHN H. LONG, M.S., Sc.D. Third revised edition. 8vo, 299 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.25.

THE NERVOUS SYSTEM OF VERTEBRATES. By J. B. JOHNSTON, Ph.D. 8vo, 370 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $3.00.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending November 17, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	373	176
Diphtheria	253	36
Measles	72	3
Scarlet Fever	115	5
Smallpox	1	—
Varicella	46	—
Typhoid Fever	108	14
Whooping Cough	90	8
Cerebrospinal Meningitis	21	8
Malarial Fever	..	.....
Totals	1079	250

Treatment of the Gastric Crises of Tabes by Elongation of the Solar Plexus.—Recently Vallas has tried the effect of the elongation of the solar plexus on the gastric crises of tabes. This method is the same as that used by Jaboulay in two cases of gastralgia. The patient of Vallas had been suffering for six years from gastric crises characterized by violent pain and incontrollable vomiting and there had been even hematemesis. After laparotomy the stomach of the patient was seen to be of normal dimensions. The appearance of very much dilated blood vessels on its surface was marked. After the pylorus was lowered search was made for the celiac trunk and the solar plexus was elongated by denuding the celiac trunk. This treatment has been followed bv entire sessation of pain on the part of the stomach.—*La Tribune Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending November 16, 1906:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
District of Columbia, Washington	Oct. 27–Nov. 3	1	..
Illinois, Galesburg	Nov. 3–10	15	..
Indiana, South Bend	Oct. 27–Nov. 10	16	.

THE TREATMENT OF DIFFUSE SUPPURATIVE PERITONITIS FOLLOWING APPENDICITIS.*

By FRANZ TOREK, A.M., M.D.,

NEW YORK

ATTENDING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL; ADJUNCT ATTENDING SURGEON TO THE GERMAN HOSPITAL; ADJUNCT PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It is only within the last decade that recoveries from more or less generalized suppurative peritonitis have occurred in sufficiently large numbers to make this malady, which formerly had an appalling mortality, appear in a brighter light. Numerous articles have been written upon the subject, showing an increase in the number of recoveries; nevertheless, the fact that a mortality as high as 30 to 40 per cent. is still reported by surgeons as representing very favorable figures, goes to show how serious is the ailment with which we are dealing.

Up to the present time I have operated in eighteen cases of diffuse suppurative peritonitis by the method described below, and I feel prompted to publish these for the reasons, (1) that I have had the good fortune of being able to save all cases operated upon not later than seventy hours after the onset of the diffuse peritonitis, and even two on the fourth day; and (2) because my method of operating differs in many particulars from that described by other surgeons. When I had operated upon my first few cases without losing any of them, I thought the result might possibly be a matter of chance or good luck; but now, after looking back upon a respectable number of cases, especially inasmuch as all of them were of a very severe type, I cannot help believing that there is something in the method of treating them that has helped to bring about this gratifying result.

In this list of eighteen cases I have had three deaths—one operated on at the end of the third day (Case 17) and two operated upon on the fourth day (Cases 14 and 18). One of these fatal cases (Case 14), a boy ten years old, was actually moribund when he was brought to the operating table. He had reached that stage in which pain ceases to be felt; as I pressed on his much distended, board-like abdomen, he declared, on being questioned, that he had no pain. A case like this one would naturally not be touched by any one whose aim is to present favorable statistics. Had it been my object to work for statistics, it would have been very easy to report 100 per cent. of cures; for, in every one of the three fatal cases operated upon at the German Hospital, I expressed my opinion to the physicians who saw them with me that I entertained no hope for their recovery, but simply operated in order to give them the only chance they could have. I may add that it is my intention to continue to operate, even in cases that are apparently hopeless, excepting perhaps those that are actually moribund, like Case 14. These eighteen cases show a recovery of 83 1-3 per cent. and a death-rate of 16 2-3 per cent. (Since reading this paper I have added three cases to my list, all of which were successful, so that the mortality has been reduced to 14 per cent.)

To appreciate what can be attained by the method which I have adopted, it is necessary to understand exactly what was the severity of the cases included in my list. By "Diffuse Suppurative Peritonitis Following Appendicitis," I mean cases of appendicitis accompanied by the presence of free pus spread over the greater part of the peritoneal cavity. Unfortunately, there is a good deal of confusion in the terminology, the same cases being described as spreading peritonitis, diffuse peritonitis, general peritonitis, etc. The reason for this lack of exactness lies in the fact that these conditions are really nothing but different degrees of the same thing, viz., of free purulent peritonitis. They might with perfect correctness all be called by the name free purulent peritonitis (peritonitis purulenta libera). But everybody knows that a case in which the pus has become widely diffused is of far more serious import than one in which it is only just beginning to spread. Clinically, therefore, we must make a distinction. The class of cases that I am reporting used to be designated as general peritonitis. This term, however, has been more and more abandoned, as in cases that are seen at operation, it is exceedingly rare that every portion of the peritoneum is involved. Some part of it will regularly be found healthy. There remain the terms spreading peritonitis and diffuse peritonitis to designate the varying degrees to which the pus has spread over the peritoneal cavity, and of these the former should be used to designate the earlier stages, the latter those in which the pus has spread over a considerable area.

It seems almost unnecessary to state, yet, to avoid misconception on the part of some, it may be well to mention that no case of abscess, no matter how large, can be classed as diffuse peritonitis. Even if the abscess extends over to or beyond the median line and up close to the liver, it is nevertheless a case of localized, not diffuse, peritonitis, if it is walled off from the rest of the peritoneal cavity. These cases are usually seen in the second week, or even later, whereas diffuse peritonitis is seen in the first few days. To be classified as diffuse peritonitis, it is necessary that the pus, or at least the greater part of it, is free in the peritoneal cavity. I say "the greater part of it," because in advanced cases of diffuse suppurative peritonitis, as a rule, a part of the pus will be to some degree, though imperfectly, separated from the remainder of it by adhesions

*An abstract of this paper was read at a special meeting of the German Medical Society, held, in honor of Professor Trendelenburg, at the New York Academy of Medicine, on April 30, 1906, and the whole paper was afterward read before the Bronx Medical Association.

between adjoining coils of intestine or between intestine and parietal peritoneum.

Whereas, the distinction between diffuse suppurative peritonitis and large abscesses is almost self-evident, it must also be understood that by no means all cases of free purulent exudate can be grouped under the caption of diffuse peritonitis. As already intimated, some excellent writers have classed all cases of free purulent exudates together, even if their extent was but limited, and described them under the name free purulent peritonitis (peritonitis purulenta libera). Or, what amounts to the same thing, cases of spreading peritonitis and diffuse peritonitis have been recorded together, and statistics have been given for a combination of the cases with an exudate of limited extent, and those with a diffuse exudate. If I had elected to include my cases of free purulent exudate limited to the right side of the abdomen and to the pelvis, or perhaps extending but slightly beyond the median line, the results would be represented by a much better figure even than the very satisfactory one given above. However, as my object is not to present statistics, but to describe an efficient method of operating in the more advanced cases, I am compelled to exclude the less extensive ones, because in these, which are correctly classed as spreading peritonitis, a different method of operating was employed. The term "diffuse suppurative peritonitis," as I employ it, refers to cases in which the free pus extended well over to the left side, a condition which was recognized, before operation, by the extent of the rigidity of the abdominal muscles and the corresponding tenderness, and was verified at the operation.

The method of operating was the following: The incision, in all but four cases, was in the median line. In two of these (Cases 12 and 13) it was about 1 to 1½ inches to the right of the median line, going through the rectus muscle; in the others (Cases 7 and 10) it was about 2¼ to 2½ inches to the right of the median line, going through the rectus fascia, but not through the muscle, this being drawn by the aid of retractors toward the median line (Kammerer's incision). The principle which guided me in the selection of the incision was to place it midway between the estimated right and left limits of the exudate, and, as in almost all the cases the exudate extended all the way over to the left, the incision naturally corresponded about to the median line.

As regards the length of the incision, it extends from the pubes to above the umbilicus, the upper limit being at least two inches above the umbilicus, usually higher. In some cases the incision extended all the way from the ensiform cartilage to the pubes. An incision from umbilicus to pubes, with which I occasionally began, proved to be insufficient for thorough work, and was lengthened upward with a detour about the navel. I have never excised the navel, as even this small unnecessary expenditure of time seemed unwarranted. The length of the incision is such that the abdominal walls may be retracted sufficiently far to allow all the affected parts of the peritoneum to be inspected.

When the peritoneum has been incised, as a rule, the pus or purulent serum at once begins to flow out; occasionally, however (Case 3), the omentum first presents through the abdominal incision and the free pus is behind it. The pus is allowed to flow out, and where it cannot flow out it is dipped out with gauze sponges or swabs that are immediately discarded. Our effort here is to do the least possible injury to the peritoneum; it is for this reason that I want as much of the pus as possible to flow out without any manipulation on our part, and recommend that the rest be dipped out, rather than wiped out, as the latter procedure would be more likely to injure the peritoneum. The less traumatism the peritoneum is subjected to, the better will be its chance to recuperate. When the bulk of the pus has thus been removed, the appendix is next exposed, a procedure by which often an accumulation of pus imperfectly separated from the rest is opened up. After having removed the appendix I flush the peritoneal cavity with large quantities of saline solution which is poured from bottles or pitchers. The flushing is done in sections, a portion of the peritoneal cavity being cleaned at a time. Thus, for instance, we may begin by washing the coils of intestine and the omentum that are eventrated. Then we may take up the region of the cecum. To cleanse this, the right abdominal wall is drawn well to the side, and while one hand, covered by a rubber glove, holds the intestine aside in one direction and again in another, the salt water is poured into all recesses in that locality. Then we may turn our attention to the pelvis. The gloved hand is introduced to the floor of the pelvis, and the intestines are drawn out of the way. The water is poured in, and the hand, by some gentle to-and-fro motions, assists it in washing all parts of the pelvis and its contents. The left iliac region may next be attended to in a similar manner, and the same process of washing is continued upward in both flanks, one portion being taken up after another, till the cavity is clean. Whenever fresh adhesions between adjacent coils of intestine are encountered, they must be loosened. By observing this precaution I have evacuated one accumulation of pus after another, where from mere inspection I would not have suspected the presence of any. This condition was probably most marked in Case 6. To anyone who has seen these collections of pus in the rear portions of the peritoneal cavity, completely covered by freshly adherent intestine, it is at once clear that the method of lavage by means of a long tube introduced through a comparatively small opening in the region of the appendix, as recommended by some, is entirely inadequate. The tube would simply pass over the intestines that cover such collections of pus, but would not come in contact with the pus that is thus partially separated from the free pus.

When the lavage has been finished, I close the abdomen completely, without drainage. This procedure in a suppurative inflammation may appear to be contrary to all recognized principles, and yet my experience teaches me that it is the proper method. If the peritoneum has not been grossly and extensively injured by the suppurative process, and if the pus has been removed as thoroughly as the procedure above described permits, the peritoneum will be able to cope with what little infectious material may yet remain behind in a considerably diluted condition. But if large portions of the peritoneum show gross changes, its recuperative powers are reduced, and recovery is less likely.

If any one is imbued with the idea that the peritoneum must be drained, he must naturally ask himself how he can accomplish it. Packing the peritoneum extensively with gauze at every possible place where there may have been pus has long been recognized as being very harmful to the integrity of that membrane; it has been shown experimentally that sterile gauze packed extensively into the peritoneal cavity of a healthy animal has caused its death. Fowler thought he had solved the problem

by draining the pelvis only, and placing the patient in an oblique plane, such that the chest is higher than the pelvis, a position which is the reverse of Trendelenburg's posture, and has been called Fowler's position. I feel quite certain that in diffuse suppurative peritonitis this posture fails of its purpose; for, although a nonirritating fluid in a noninflamed peritoneal cavity will tend to accumulate at the lowest part of the cavity, such is not the case in peritonitis with pus. The peritoneal surfaces are in a short time incited to form adhesions which will prevent the downward flow of the purulent serum. The very course of appendicitis with pus speaks against Fowler's principle, inasmuch as at the operation the pus will most frequently be found to have spread in the direction in which the appendix happens to lie, whether that be upward, downward, or across. According to Fowler's principle, if a patient's appendix, or appendicular abscess, ruptures, while he is still up, either sitting or standing, we ought invariably to find pus in the pelvis; and we know that this is not always the case. Even in the case of ascites, where we have a bland fluid, all the fluid will not invariably find its way to the lowermost part; portions of the exudate will at times be sacculated, as is occasionally seen when we perform a laparotomy in the presence of ascites. Fowler's position, I should say, may be of some value in very recent cases of pyoperitoneum, where the peritoneum is as yet but slightly congested—in a word, in just those cases where the advice to omit drainage will be best understood and most readily concurred in; but in more advanced cases of diffuse suppurative peritonitis it certainly fails to accomplish its object. In the majority of my cases I would not have dared to raise the patient's head, owing to danger of syncope; in fact, in a number of these cases, I have had to elevate the foot of the bed, owing to the profound depression of the heart's action.

In two of my cases, during convalescence, localized intraperitoneal abscesses occurred, which manifested themselves by pus oozing from one or two stitch canals. It is particularly noteworthy that in neither of these two did the abscess form near the cecum or in the pelvis, the regions where drains would have been placed by the advocates of drainage. In one case (Case 6) a localized abscess formed in the left lateral abdominal region, about on a level with the umbilicus, and in the other (Case 10) it formed at about the same level, just to the right of the median line. If one had decided to employ drainage in either of these cases, one would surely not have drained at the site where the abscess subsequently developed, and, as all other parts of the peritoneal cavity remained clean, one would only have done harm by draining where no drainage was needed. These cases particularly showed that in diffuse suppurative peritonitis we simply cannot tell where we should drain, and it is better not to drain at all than to run the chance of doing harm by drainage at the wrong place.

In four cases (Cases 1, 11, 12, and 13) I had extraperitoneal suppuration of greater or less extent in one or other layer of the abdominal parietes, the most extensive one being in Case 13, where the incision through the right rectus had been chosen. In this case I had been particularly careful to protect the abdominal wound against infection from the outflowing pus by placing gauze over it. The very long incision through a thick muscle doubtlessly exposes a larger wound surface to infection than an incision in the median line. I would therefore not recommend it.

Of the remaining nine cases, two or three showed signs of inflammation at the stitch canals, which subsided promptly on removing the stitches; the remaining cases healed without the slightest sign of irritation.

The closure of the abdominal wound was performed in various ways: through-and-through suture, suture of each layer separately, and thirdly, suture of the peritoneum separately with a superimposed combination suture of skin, fascia, and muscle. In one case in which I employed the last of these methods, I cleansed the abdominal wound very carefully after closing the peritoneum, hoping that in this manner I would prevent the formation of a mural abscess; but the infection of the abdominal wall nevertheless occurred. I have used most frequently, and am now using exclusively, through-and-through silk sutures, as they can be put in most rapidly, and rapidity in performing the operation certainly counts for something, although it should not be overestimated. Rapidity at the expense of thoroughness in cleaning the peritoneal cavity may appeal to those who dread the specter of a death on the operating table, but it will cost a number of lives after the operation. The shortest time in which I have been able to perform the operation is twenty minutes; the longest time was one and a half hours. In this case of long duration a complete eventration was necessary, and enterotomy had to be practised at three different places to empty the distended bowels and get them back into the abdomen.

Some two years ago a paper on this subject was read at the New York Academy of Medicine, in which a rather small incision, lavage through a metal tube, and drainage in Fowler's position, were recommended. The paper was discussed by a number of eminent surgeons, who concurred with the reader of that paper in the principles he had laid down. I alone dissented, and recommended large incisions and flushing by pouring, and even advanced the heretic principle, based on my experience, that drainage was not needed, if the peritoneal cavity had been washed clean. It has given me great satisfaction to learn that now a number of surgeons are beginning to share my views in regard to the question of drainage.

The after-treatment demands careful attention. All these cases require hypodermic stimulation, strychnine, digitalis, and camphor, occasionally caffeine and nitroglycerin, being the drugs I usually employ. In cases with severe shock saline infusion is given, adrenalin is administered, and the foot of the bed is elevated. Hypodermoclysis is an excellent method of introducing fluids when the stomach is not capable of retaining them. The introduction of fluids in this manner, or by infusion, also counteracts sepsis, as it encourages the elimination of poisons by the kidneys. Vomiting is treated by lavage of the stomach. I attach considerable importance to this procedure, and I believe that it has saved a few lives. For pain, enough morphine is injected to make the patient fairly comfortable. As a rule, these patients do not pass gases spontaneously during the first two days; sometimes even not for four days. To relieve them the rectal tube is inserted frequently. This may give but a moderate degree of relief; nevertheless, in these first few days, I do not recommend the employment of any of the more active means of encouraging peristalsis, such as cathartics or enemata. I know that in this respect, again, I am at variance with the views of the majority of physicians, who hold that the bowels must be moved early, in order to avoid intestinal paralysis. This practice may be very good after clean laparotomies,

for it certainly makes the patient feel easier; but where the intestines are affected by an inflammation of their peritoneal covering, they should be allowed to rest for a few days, in order that they may recover, particularly, also, that adhesions may form around the stump of the appendix. After a lapse of three, or preferably four days, if the patient still suffers from an imperfect evacuation of gases, I employ a lavage of the rectum, the water being allowed to enter and flow out again, without any attempt to force it up the intestine. A regular enema is given about the fifth or sixth day. A study of my cases would substantiate the correctness of the view that the intestines should be permitted to rest during the first days. All of my successful cases, except the first one, were treated in accordance with this principle, no attempt being made to move the bowels. My first case had magnesium sulphate introduced when the stomach was washed. As regards the three fatal cases, No. 14, the moribund one, can be disregarded; No. 18, in which the progress of the sepsis was not even interrupted by the operation, also has no bearing on this question; Case 17, the remaining fatal case, received an enema daily, beginning with the day following the operation. Just at that time I had read articles by several writers on this subject, in which it was strongly recommended that peristalsis be induced as soon as possible after the operation. This caused me to waver from my usual method and to order the enemata in Case 17. The effect at first was surprisingly satisfactory, as the patient felt very well after his enemata; but on the sixth day he suddenly developed a septic peritonitis, which, within less than half a day, caused his temperature to rise 7½ degrees, and terminated fatally. I cannot help thinking that the excitation of peristalsis prevented the formation of firm adhesions over the stump of the appendix, that on the sixth day the closure of the stump became imperfect, and that fecal matter discharged itself over the peritoneal cavity. It was impossible to prove the correctness of this view, as an autopsy was not permitted. If it were within our power to bring on a movement of the bowels with a very slight amount of peristalsis, I should give my consent to the administration of such a remedy; but as long as the degree of peristalsis is not completely in our control, I prefer to leave the bowel alone.

(Since reading this paper I have had the opportunity of assisting another surgeon at an operation for diffuse suppurative peritonitis in a female child, a case about equal in severity to the milder ones in my series. Two days later I saw her again in consultation. In the meantime, calomel had been given, and her bowels were moving freely. She appeared to be in satisfactory condition and was feeling comfortable—like my Case 17. But on the following day she sank rapidly, the temperature rose, and she died of septic peritonitis. So my experience with exciting peristalsis after this operation leads me to consider it a dangerous procedure.)

For a similar reason I do not give rectal alimentation in these cases, as this is apt to excite peristalsis. I give small quantities of water, if the stomach will bear it, and later bouillon and strained gruel. If the stomach revolts and the patient vomits, the stomach is washed, and again nothing but water is given for a short time.

As regards the prognosis, it may be said in a general way that the earlier a case comes under treatment the better the chance for recovery; it will be best, if the pus has not yet spread far enough to classify the case under diffuse suppurative peritonitis. Nevertheless, the severity of the case cannot be measured by any such routine method as the number of hours it has lasted. Some cases progress more slowly than others. If this were not so, it would not have been possible for me to save some cases operated on the fourth day, while one, operated at the end of the third day, succumbed. In cases that progress more slowly we find at the operation that here and there the peritoneum tried to set a barrier to the invasion by forming adhesions which would hold back the pus in one direction, but fail to do so in another direction. I have found that these adhesions are usually formed anteriorly, while posteriorly the pus travels onward. Thus we not infrequently find some adhesions in the neighborhood of the appendix which may have prevented the pus from at once finding its way upward; in such cases it frequently travels next into the pelvis; here, again, some adhesions may imperfectly close the pelvis, the pus, however, continuing to travel to the left iliac fossa, and so on. In one patient (Case 11) the adhesions in the region of the appendix and at the brim of the pelvis had even attained quite some firmness, yet they did not prevent, but they merely retarded the progress of the pus, as in that very case the abdomen was full of it up to the liver and spleen. Such a case in which the disease advanced more slowly may be more favorable on the third day than another case with a more rapid invasion on the second day.

To sum up, the main points recommended in the treatment of diffuse suppurative peritonitis are: 1. Extensive incision, as a rule in the median line; 2. Lavage with saline solution poured in large quantities into the peritoneal cavity; 3. Closure without drainage.

The following is a list of my cases, almost all of which were operated upon at the German Hospital.

Case I. Miss T. F., 22 years old, was admitted to the German Hospital on June 9, 1902, at 10 P.M., complaining of severe abdominal pain. Her pulse was 126, her temperature 104.2°, and her respiration 36. When I saw her half an hour later I found a little woman with flushed cheeks, rapid and shallow respiration, an expression of the face that indicated suffering, yet taking scarcely any interest in her surroundings. Her pulse had in the meantime risen to 140 and the respiration to 40; she was in a somnolent state, but answered questions quite rationally. She said that for a few days she had suffered pain extending over the greater part of the abdomen, that the pain, however, had become much more severe in the last twenty-four hours, and that her abdomen had swelled up in that time. Upon examination the abdomen was considerably distended, the abdominal wall was rigid, and there was very marked tenderness on pressure, especially in the epigastric region. The diagnosis of diffuse peritonitis was evident from these symptoms, but the source of the infection was obscure. Of course, my first thought was of appendicitis, that being the most frequent cause of general peritonitis, and consequently I tested repeatedly, and with the utmost care, whether the region of the appendix were not the seat of greatest tenderness. But the patient's statement that the upper half of the abdomen was more tender than the lower could not be shaken. The tenderness, moreover, was equally great on the left side as on the right. The indefinite history of the malady previous to the patient's admission to the hospital was also inadequate to throw any light upon the nature of the primary trouble.

The operation was performed after midnight. A median incision was made from the ensiform cartilage to the umbilicus. As soon as the peritoneum

was opened a seropurulent fluid ran out immediately. To find the source of this I first examined the gall-bladder; this contained a stone, but showed no lesion. The transverse colon and the hepatic and splenic flexures were found intact, as were also the stomach and the duodenum. The incision was thereupon extended to near the pubes, and the intestine was completely eviscerated, beginning at the duodenum, loop after loop being carefully inspected. Finally, as the iliocecal valve was reached, a distinct fecal odor gave proof that the intestine was the source of the suppurative peritonitis. The appendix was considerably distended, measuring about one and a quarter inches in diameter, and presenting perforations at about its middle, and near the apex. A fecal concretion was found in the neighborhood of the appendix. Loose adhesions had formed between the cecum and the abdominal wall, shutting off the general peritoneum above and to the medial side; the infection, however, had descended into the pelvis, and had thence traveled upward into the general peritoneal cavity. The appendix was now resected and the peritoneal cavity very energetically flushed with saline solution. On trying to close the abdominal parietes, it was found impossible to replace the enormously distended intestines. Accordingly the gut was incised and gas and fluid contents allowed to escape, to diminish its bulk, the small incision being promptly closed by Lembert sutures. This procedure had to be done at three places before the intestines could be replaced. The abdominal wall was then completely closed without drainage. The sutures were rapidly inserted in three layers, (1) peritoneum, (2) fascia and muscle, (3) skin. At 1:45 the patient was in bed again.

For about thirty-six hours after the operation the patient looked very sick indeed. Nevertheless, her pulse and temperature gradually went down, the highest temperature on the first day following the operation being 103.2° and the highest pulse 120. She was stimulated hypodermatically with digitalis, caffeine, camphor, and nitroglycerin interchangeably, at first every half hour, afterwards less frequently. Owing to the persistent vomiting, the stomach was washed about twelve hours after the operation. After the lapse of another twelve hours it was washed again, and an ounce of magnesium sulphate was introduced into it through the tube. This resulted a few hours later in a small movement of the bowels. On the following day the same procedure was resorted to, and again a movement of the bowels was the result. On the first and second days the patient was very restless and vomited frequently, but on the evening of the second day she began to improve, the highest temperature on that day being 102.2° and the highest pulse 112. From that time on her recovery progressed steadily, being interrupted only by the formation of an abscess in the line of the incision from infection through stitch canals. This was opened in the course of the second week, and the temperature subsequently remained normal. The patient was discharged cured on July 19.

A point of particular interest in this case is that the place where tenderness was greatest did not coincide with the site of the appendix, and was therefore a misleading factor in the diagnosis. In regard to this I may say that occasionally the pain and tenderness are greatest at the site of the most recent invasion. As regards the administration of the cathartic, which I do not now recommend, it will be noted that in this case the action was very mild. If it had been more drastic I believe it would have done harm rather than good.

In October, 1903, the patient came back to be operated upon for a ventral hernia which had formed in the scar. At this operation I made the interesting observation that her peritoneum was almost entirely free from adhesions. Maydl's operation was performed, and resulted in a good, strong union. The patient has since been married, and has gone through a pregnancy without in the slightest degree weakening the scar.

Case II. E. F., female, thirteen years old. Very fat little girl. No history of previous attacks. Severe pain at site of appendix began on September 30, 1902, two days before operation; exact hour not certain, but believed to be nearly forty-eight hours before operation. Examination revealed very severe pain on both sides of the abdomen, most severe over the appendix, extending somewhat above the navel. These parts were rigid. The epigastric and uppermost parts of the hypochondriac regions were but slightly tender and rigidity less marked. Temperature 103.2°, pulse 156, respiration 40, mainly costal. Cheeks flushed with fever, and, as they were very fat she did not at first impress one as a very sick child, but she had an unsteady look, and moved her head and extremities restlessly. Operation October 2, 1902. Median incision from two inches above the umbilicus to the pubes. Free pus at once escaped from both sides of the abdomen. At the site of the appendix adhesions were severed, behind which there was a collection of pus, thicker than the free pus encountered at first, and having a markedly feculent odor. The appendix was about three times its normal thickness, bluish red, and presented several gangrenous spots, one of which was perforated, a fecal concretion protruding half way through the opening. The appendix was removed and its stump charred. Lavage as in Case 1. Through-and-through silk sutures. No drainage. Recovery uninterrupted. Healing without suppuration. Stitches removed on the thirteenth day.

Case III. L. M., male, twenty-eight years old. History of three previous attacks. Fourth attack began on November 25, 1902. It was more severe than the previous attacks, but on the following day he improved. On November 28, in the evening, his pain became exacerbated and more extended, and got still worse on November 29. When seen early on November 30 his abdomen was rigid throughout and very tender, except at the uppermost part. Rectal examination was very painful, and revealed nothing. Operation on November 30 at 7 A.M., thirty-four hours after the onset of his severe pain. Median laparotomy from 2½ inches above the umbilicus to the pubes. On opening the peritoneal cavity, first at a place midway between the umbilicus and the pubes, the omentum was found adherent to the abdominal wall. On loosening it the pus gushed out from all sides. It seemed as if an attempt on the part of the omentum had been made to obstruct the extension of the pus, but, instead of encapsulating the pus, it only succeeded in protecting the anterior parietal peritoneum, while behind the omentum the infection extended without restraint. The pus was allowed to flow out; then the appendix, which was perforated near its origin, was removed. Thorough lavage with salt water poured from pitchers. The saline solution in this case was not as warm as it should have been; in fact, it appeared to me to be cooler than the body temperature, so that I had some misgivings as to the possible injurious effect. But the further course proved that no harm had been done. The wound was closed, without drainage, by through-

and-through silk sutures. Healing by primary union.

Case IV. G. C., female, twenty-three years old. Admitted January 18, 1903. Two days ago she began to suffer from pain in the right iliac region, followed shortly after by vomiting. On the following day she had a movement of the bowels, but the pain, instead of subsiding, increased, and spread over the whole abdomen. On admission her temperature was 103°, the pulse 120 and small. Leucocytosis 24,400. Abdomen rigid throughout, tender everywhere, exquisitely so at the region of the appendix; tympanites as high up as the ensiform cartilage. Operation January 18, 1903. Median incision from two or three inches above the umbilicus to the pubes. Thin purulent serum evacuated. Small perforation in appendix. No adhesions anywhere. Lavage with saline solution; closure by layer suture; no drainage. The patient did very well from the start. Her temperature dropped at once after the operation, and then never rose above 101.4°. Although the bowels did not move after the operation, they were not interfered with for four days, when two lapactic pills and an enema were ordered. The wound healed by first intention. This case differed from most others in the fact that there was not an adhesion in the peritoneal cavity, the only visible changes in the peritoneum being an intense injection of the vessels.

Case V G. R., male, twenty-seven years old. Operated upon on April 13, 1903. History of four previous attacks. Thirty-one hours ago he experienced a sharp pain in the right iliac region, and he vomited soon after. Did not send for a physician till next day, when the pain spread over the greater part of the abdomen. The case was recognized as appendicitis, and operation was advised. Examination revealed rigidity and great tenderness over the lower two-thirds of the abdomen. The incision at first made from the umbilicus to the pubes. Pus flowed from both sides, as well as from below and above. The incision was then lengthened to two inches above the umbilicus. There were slight adhesions above the appendix, which was perforated, and presented a few gangrenous spots. Appendix removed; lavage as in the other cases; through-and-through silk sutures; no drainage. Recovery uneventful.

Case VI. A. B., female, ten years old. Admitted to the hospital August 30, 1903. Had an attack of appendicitis two months ago, lasting three weeks. Again became sick yesterday at 4 P.M. with severe chills and intense abdominal pain. Her mother gave her castor oil, which brought on a few watery movements. She also had some pain on urinating. This morning the pain had diminished, but the patient became listless, and looked much worse. At 4 P.M. to-day, on admission to the hospital, the abdomen was found rigid on both sides, especially about the middle of both recti. The house surgeon also took a note that an area of dullness, extending from the right Poupart's ligament to the liver, would shift with a change in the patient's position, indicating the presence of free fluid. The temperature at 4 P.M. was 103.8°, the pulse 144, respiration 36. At 6 P.M. the temperature had gone down to 103.2 degrees, the pulse to 140, and the respiration to 28, but the rigidity of the abdomen was about the same, and the general condition no better. Operation was performed at 8 P.M. Median incision from near the sternum to the symphysis. Pus flowed out as soon as the peritoneum was opened. The appendix, which was thick and presented a gangrenous area near its origin, was removed, and the stump charred. Pus was found in all parts of the peritoneal cavity, on the surface, in the pelvis, underneath the liver, under the diaphragm, near the spleen; a particularly large amount welled up from the duodenojejunal fold; wherever the adjacent coils of intestine were separated pus welled out. These adhesions just referred to were quite recent, and were easily separated by the mere handling of the intestines. Salt water was poured in from pitchers until the fluid remained clear. A considerable amount of salt water was left in the abdominal cavity. The wound was closed entirely, without drainage, by stout through-and-through silk sutures. After the operation the patient received a hypodermic injection of three minims of Magendie's solution and a saline enema of 120 c.c., containing 20 c.c. of whiskey and 1-30 grain of strychnine. The hypodermic stimulation was administered, consisting of the following: Fluid extract of digitalis, 1 minim; camphor oil, 10 minims; strychnine sulphate, gr. 1-50; caffeine benzoate, 2 grains. These were given in alternation, so that one injection was given every hour. On the following day the patient felt very much brighter, and was willing to talk and answer all questions. The hypodermic stimulation was now given every two hours, and a saline enema of 150 c.c., containing 15 grams of whiskey, was given every six hours. The patient having vomited some dark-brown fluid, her stomach was washed out. On the third day she did not vomit any more. An enema was now given, which was followed by a number of movements. She kept on improving, her highest daily temperature after the operation being between 101° and 102°. Stimulation was gradually diminished. On the fifth day pus was seen to appear through the second stitch from above. Later on one of the lower stitches discharged pus; then pus came from nearly all of them. On the seventh day some stitches at the lower end of the wound were removed, in the expectation that the pus came from a site near the stump of the appendix, but it proved that the pus at this place did not come from the peritoneal cavity, but from above the fascia. On September 11 a large quantity of pus was discharged at a place above the umbilicus, evidently coming from the peritoneal cavity. On the following day this place, above the umbilicus, was opened more widely under anesthesia. It led into the peritoneal cavity to the left and upward. A large drainage tube and some gauze were introduced. On September 20, and a few days following, some feces were discharged from the wound. On September 24 no more feces were found, and the wound became clean. The further course was uneventful. The patient was discharged cured on October 27.

Case VII. Mrs. K. D., thirty-nine years old. History of a slight attack six weeks ago. The present attack began November 29, 1903, with severe pain in the right iliac region, and later on became generalized. She had no chill. She was nauseated, but in the beginning did not vomit. She had diarrheal stools. Later on the pain became worse, the fever rose, vomiting set in, and was followed by general depression. When seen on November 30 her tongue was dry and coated, the abdomen extremely tender, especially in the right iliac region. There was general rigidity, which, however, was less marked on the extreme left of the abdomen. Great tenderness on rectal examination, especially toward the right. Temperature 102.6°, pulse 116. Operation November 30, 1903, sixteen hours

after the beginning of the attack. As the rigidity was comparatively slight at the extreme left border of the abdomen, I concluded that that part was not yet invaded, and therefore made my incision to the right of the median line, judging that this would be about midway betwen the right and left limits of the pus. The right rectus incision (Kammerer's) having been made, my assumption proved to be correct. The free seropus, which at once flowed out, extended to within three inches from the left border of the peritoneal cavity. With that exception, the whole abdominal and pelvic cavities were full of a thin seropus. The appendix, which had a small perforation, was removed. Lavage with saline solution. Layer suture. No drainage. Her recovery was rapid. The temperature became normal on the fourth day, and remained so. Gas was not expelled till the second day after the operation, although the rectal tube was introduced. The bowels did not move until the fifth day, when an enema was given. Healing by primary union.

Case VIII. L. H., female, seven years old. The patient was attacked with appendicitis in the course of a tonsillitis which began on December 20, 1903. On December 23, while the throat was improving, she complained of abdominal pain, mainly on the right side. This pain became more generalized, but later on again became localized on the right side. The patient felt fairly well, and, contrary to the family physician's orders, left her bed, and was also up a good part of the following day, December 24. On that day, at 6 P.M., the abdominal pain suddenly became very severe, especially on the right side. Some distention of the abdomen set in. There was no vomiting. On December 25 her general condition became poorer, the abdominal pain increased, the distention became more marked. The family physician advised operation, and the patient was taken to the hospital. On admission there was still a little exudate on the left tonsil. The expression on the patient's face was anxious and her appearance that of a septic case. The abdomen was distended and tympanitic. Tenderness and rigidity were found over the entire abdomen, except in the splenic and epigastric regions, but they were more marked on the right side than on the left. Tenderness was most marked above the right Poupart's ligament, where an indefinite mass could be felt, and a dull percussion note was obtained. Per rectum, distinct bulging was found on the right side, and tenderness was extreme. Pulse 136, temperature 103°. Operation on December 25, 1903, at 8 P.M., twenty-six hours after the onset of the diffuse peritonitis. Median incision from about three inches above the umbilicus to the pubes. Seropus at once exuded from both sides of the median line. The pus was diffused through the greater part of the abdominal cavity and the pelvis. No adhesions anywhere except in the right iliac fossa, where the small intestines and the cecum were matted together by rather fresh adhesions. On separating these a large abscesss, containing thick yellow pus of a fecal odor, was opened. At the bottom of the abscess was the appendix, 2½ inches long, pointing downward, and inward, adherent to the posterior wall of the abdominal cavity. It was perforated near its base at the side opposite its mesentery. After its removal the peritoneal cavity was thoroughly washed with saline solution. The abdominal wall was closed by through-and-through silk sutures, without drainage. On the following day she vomited five times. Lavage of the stomach was resorted to, after which the vomiting did not recur. She improved steadily. Her bowels were moved on the fifth day by an enema. Her recovery was uneventful, except for the occurrence of stitch abscesses, which cleared up promptly after the stitches were removed on the fourteenth day.

Case IX. J. R., male, thirty years old. No history of previous attacks. On March 15, 1904, pain in the right iliac region, which subsided almost completely on the next day, leaving only slight tenderness. On March 20 the pain became very severe, and extended to other parts of the abdomen. The patient became nauseated, but did not vomit. Rectal and vesical tenesmus set in. On examination, March 21, his abdomen was rigid, distended, and very tender. The rigidity, though more marked on the right side, extended well over to the left border of the abdomen. The tenderness appeared to be greater on the left side than on the right. At the uppermost part of the abdomen the tenderness was but slight. On rectal examination, a mass was felt to the right and posteriorly. This examination was quite painful. Temperature 102.8°, pulse 122, respiration 28. Operation on March 21, twenty-five hours after the onset of diffuse peritonitis. Median incision from 2½ inches above the umbilicus to the pubes. Thin pus ran out. Adhesions walled off the region of the appendix. On severing these thick pus was found. The partly gangrenous appendix was removed and the peritoneal cavity washed with saline solution. Pus was found in the pelvis, in the left iliac region, as well as the right, and in both lateral abdominal regions. The peritoneum was extensively injected. Closure of the abdominal wall by through-and-through silk sutures. No drainage. Healing without suppuration.

Case X. R. H., female, nineteen years. Was attacked with very severe pain in the right iliac fossa on April 22, 1904, at 8 P.M. Did not sleep all night. Vomited next day and the day following. On the morning of April 25 she had a chill lasting almost an hour, followed by fever and sweating. Her condition grew steadily worse. On examination a slight bulging was found in the right iliac fossa, where a tense mass could be palpated, and dullness was obtained on percussion. Tenderness and rigidity were greatest at this place, but also well marked higher up, and on the left side about as far as four inches beyond the median line. There was tenderness on rectal examination. Temperature 104.6°, pulse 124, respiration 24. Operation on April 25, 1904, at 10 P.M., seventy-four hours after the beginning of the disease and seventeen hours after the prolonged chill which marked the onset of the diffuse peritonitis. Right rectus incision (Kammerer's). Free seropus ran out from all sides. In the right iliac fossa adhesions covered a collection of thicker pus. Removal of the appendix which was covered with a fibrinous exudate. Lavage with saline solution. Closure of the wound in layers. No drainage. The patient recovered nicely. She received an enema on the third day. On the eighth day the temperature rose again to 102.8°, and on the following day a well defined mass was felt to the right of the upper part of the incision. On May 6 this was opened under anesthesia by going through the old scar. Many adhesions between coils of intestine were encountered. These were separated, and an abscess was evacuated. Hereafter the recovery was undisturbed.

Case XI. M. M., female, twenty years old. On June 17, 1904, she began to have abdominal pain, which became severe on the following day, and con-

tinued to increase until the operation, four days after the onset. On examination, June 21, the abdomen was found hard and uniformly distended. The umbilicus protruded. On percussion the resonance was very tympanitic, except at the right inguinal region, where the note was more dull. Both recti were rigid, the right more so than the left. No distinct mass could be felt, but there was a sense of resistance in the right iliac fossa. Tenderness on both sides, most marked in the right lower quadrant. Leucocytes 28,000. On admission to the hospital at 12 M., the temperature was 101.2°, the pulse 116, respiration 28. Two hours later the temperature was 102°, pulse 124, respiration 30; at 4 P.M., temperature 102.8°, pulse 136, respiration 32. Operation at about 4:30 P.M. Incision from midway between ensiform cartilage and umbilicus to the symphysis. The intestines were distended; turbid yellow fluid welled up from the pelvis. A large abscess was found in the right iliac region; more pus was found in the pelvis, behind the uterus and in front of it, and in the left iliac fossa. These were so well walled off anteriorly that quite some force had to be used to loosen adhesions, but posteriorly and upward no adhesions could be found. The upper coils of intestine, which appeared to be clean, were covered with gauze pads, and then the pus was flushed out with salt water poured in from pitchers. It was then seen that the pelvis and the adjacent coils of gut were covered with a thick fibrinous deposit. The appendix was gangrenous; it was ligated, removed, and the stump seared with the pacquelin. Closure by through-and-through silk sutures. No drainage. The patient was at first stimulated with fluid extract of digitalis, 2 minims, strychnine sulphate gr. 1-30, camphor oil, 15 minims, alternately every half hour, the stimulation being gradually diminished as the patient improved. On the first three days Magendie's solution was also given as needed, from 12 to 14 minims a day. The rectal tube was passed on the second and third days, evacuating some gas. On the fourth day the bowels moved spontaneously. On June 26 a few stitch canals at the lower angle of the wound were reddened, and a small area of skin was gangrenous. A moist dressing was applied. On July 3 the gangrenous tissue had sloughed off, leaving an irregular wound. All the stitches were removed. On July 16 she got up, with a clean, granulating wound, and was discharged on July 24.

It is difficult to say in this case when the diffuse peritonitis commenced, but it was quite evident that, as the pus progressed from one section to another, from the right iliac fossa to the pelvis and thence to the left iliac fossa, the peritoneum at each of these sections made a rather strong, yet unsuccessful, effort to localize the process, until finally it became diffuse.

CASE XII. J. M., female, nineteen years old. Cramps and abdominal tenderness began July 14, 1904, accompanied by vomiting, and increased up to the time of the operation, July 16. The patient, a well-nourished, somewhat corpulent person, with slightly distended abdomen, presented a slight bulging to the right of the umbilicus, and just below its level. Here a mass of the size of an orange was felt, the tenderness being very great. Both recti were tense, the right more than the left. Per rectum, some bulging was found in Douglas's cul-de-sac. In the next few days the area of tenderness had extended to the right hypochondriac and the upper part of the umbilical region; the abdomen was also somewhat more distended. Incision through the middle of the rectus, parallel to its fibers. A large quantity of seropurulent fluid welled up. The appendix was on the medial side of the cecum, surrounded by omentum. On liberating this a small pus cavity was opened. The appendix was gangrenous in its entire length, and was perforated near its base. It was removed and its stump seared with the paquelin. Lavage with hot saline solution. Closure by through-and-through silk sutures. No drainage. Stimulation with strychnine and digitalis in alternation was given every two hours for more than three days, and was then diminished. Morphine was given as needed for three days. Gas was passed on the second day; the bowels were moved by an enema after four days. The wound margins in the lower part became gangrenous, and the greater part of the wound suppurated. It was treated by separating the edges of the wound where necessary, and tamponing with sterile gauze. The wound soon cleaned up and filled with healthy granulations.

CASE XIII. A. H., male, forty-two years old Had two previous attacks, a short one in 1903 lasting one day, and another in 1904, lasting about a week. On February 8, 1905, he was seized with cramp-like pains in the abdomen after the ingestion of rhubarb. His condition gradually grew worse, and toward evening became unbearable. On admission to the hospital, February 9, 1905, he was suffering intense pain. The expression of his face was pinched, the tongue heavily coated and dry, the abdomen considerably distended. There was tenderness over the entire abdomen, more particularly over the right iliac fossa. The abdominal muscles were rigid, only at the extreme left they were somewhat less resistant. Temperature 101.8°, pulse 108, respiration 30. Operation on February 9, at 8:30 A.M., about seventeen hours after the onset of the diffuse peritonitis. Incision through the right rectus, about 1½ inches to the right of the median line, and parallel to it, a large amount of purulent fluid escaped, coming from all directions. The appendix pointed upward and backward, and was imbedded in omentum. At its tip there was a small gangrenous area. It was tied off, removed, and the stump charred. Lavage with saline solution. Closure of the abdominal wall in layers, without drainage. The patient vomited frequently on the following two days. He passed gas readily when the rectal tube was introduced. The bowels were moved after six days by an enema. This patient, while his peritoneal cavity remained clean, developed a most extensive suppuration of the abdominal wall, causing sloughing of a large portion of fascia. The skin wound had to be opened almost in its entire extent, and a counter incision had to be made on the right side. The wound healed by granulation.

CASE XIV. C. K., male, ten years old. On July 23, 1905, he began to complain of pain over the entire abdomen. With very short intermissions the pain continued till his admission to the hospital on July 27. His features were pinched (facies hippocratica), the color of his face was slightly bluish; his eyes were at times somnolent, at times unsteady; his abdomen was widely distended, the muscles tensely contracted. Temperature 104.6°, pulse 156, respiration 40. His sensibility was reduced. He was in that stage of peritonitis in which severe pain is no longer complained of; on being questioned, he declared that he had no pain. In a word, he was moribund. Although I recognized this condition, and stated that I was practically sure

he would die, I determined to give him the only possible chance, and operated. Complete median incision. Pus in enormous quantity was found distributed throughout the peritoneal cavity. Removal of the appendix which was found in the pelvis perforated. Lavage as usual. Closure without drainage. The patient gradually sank, and died two hours later.

Case XV. F. N., male, fifteen years old. On December 9, 1905, he began to have pain over the entire abdomen, most marked in the right iliac fossa. Cathartics were given, but the pain, instead of letting up, increased. On admission to the hospital, December 12, his abdomen was very sensitive and rigid on both sides; only at the uppermost portion the pain was less marked. The greatest sensitiveness was at the region of the appendix. Rectal examination was very painful, particularly on pressure against the anterior wall. Operation on December 12, seventy-five hours after the beginning of the peritonitis. Median incision from 2½ inches above the umbilicus to the pubes. Pus flowed out from all sides, and could be followed to the extreme left of the peritoneal cavity. Here and there adhesions were found between coils of intestine, behind which pus was found. The strongest adhesions were above the appendix, which was perforated and partly gangrenous, and presented a fecal impaction through its perforation. Removal of the appendix. Lavage with saline solution. Closure with through-and-through silk sutures, without drainage. Healing by primary union.

Case XVI. Mrs. W. L., thirty-four years old. On January 10, 1906, she began to have a sudden pain in the abdomen, which gradually increased and extended from the epigastrium to the pubes. Next day the pain was more pronounced in the right iliac fossa than elsewhere. A cathartic was given, causing many movements of the bowels. On admission to the hospital, January 12, her face had a drawn, anxious expression; her eyes were bright, restless, alert; her tongue was dry and coated with brown crusts. Her pulse was 136 and very small, but regular; respiration 36, entirely costal; temperature 102.6°. Abdomen everywhere rigid and painful on pressure. Rectal examination painful. The patient's appearance was so alarming that she was sent at once from the examining room to the narcotizing room, and was operated within an hour of her admission, fifty-three hours after the beginning of the peritonitis. Incision in the median line from near the ensiform cartilage to the pubes. Free pus extended all the way over to the left iliac fossa and above the umbilical region. The appendix was thick, reddish brown, gangrenous. It was ligated, removed, and its stump charred. Lavage of the entire peritoneal cavity. The patient's condition was very bad throughout the operation. While lavage was being performed, the pulse, which had been extremely weak all along, could not be felt any more, and she stopped breathing. A cadaverous pallor at the same time made it appear as though she had actually died on the table. The operation was continued, however, with the utmost despatch, while one assistant was making artificial respiration, and another one prepared to give a saline infusion. After a few minutes the patient began to breathe again. A few through-and-through silk sutures were introduced to close the abdomen without drainage. The venous infusion was given, and the patient gradually recovered from her shock. For a few days after the operation the temperature remained high, reaching 105° on the sixth day; then it gradually dropped, till from the tenth day on it was fairly normal. The pulse remained weak for a long time, and required a good deal of stimulation. She passed gas on the second day, and her bowels moved on the fourth day. The wound healed by primary union throughout, only a little redness appearing at a few stitch canals, which subsided on applying moist dressings. The stitches were removed after fourteen days.

Case XVII. G. T., male, thirty years old. Operated on March 26, 1906. His abdominal pain, which was very severe from the start, began seventy hours before the operation. On admission to the hospital he had an anxious expression, his abdomen was rigid on both sides. Tenderness was extreme, except at the uppermost part, where it was less acute. Pulse 120, temperature 103°, respiration 32. The pulse was very weak. The patient looked septic. A bad prognosis was given. Median laparotomy from four inches above the umbilicus to the pubes. Pus escaped from both sides. On approaching the appendix more pus welled up. The appendix was extensively gangrenous; a few fecal concretions lay near it. It was removed. Pus escaped from the pelvis, from the left iliac fossa, from both flanks, from under the transverse colon, from behind the liver. Lavage with saline solution. Through-and-through silk sutures closed the abdomen without drainage. Time, twenty minutes. After the operation the patient's temperature declined, and on the third day reached the normal. On the second day, and each day thereafter, an enema was given, and this resulted in the discharge of gas and feces. For five days the patient did very well. On the sixth day, after having felt quite well in the morning, his temperature rose from 98.6° rapidly and steadily to 106.1° at 4 P.M., and at 5:30 he died. His appearance was that of an acutely septic case. About noon he had vomited a large amount of brownish fluid, which, unfortunately, was not kept for laboratory examination. An autopsy was not permitted.

Case XVIII. W. A., male, twenty-six years old. Admitted to hospital April 16, 1906. Had one previous attack in February, 1906, lasting ten days. This attack began on April 12, 1906, with slight colicky pains on both sides, followed by vomiting. Next day the pain was very severe, especially on the right side; it spread more and more. He vomited every day since the beginning of the attack, and belched continuously. He never had any chills, but had fever. His bowels did not move, although he had three injections; these were returned clear, with the discharge of a considerable amount of gas. Micturition was difficult to start. On admission to the hospital he looked very low indeed. His face was flushed, his conjunctivæ slightly jaundiced, his tongue very much furred. Pulse, 116, rising after a few hours to 154; temperature 101.2°, rising in a few hours to 103.4°; respiration 28, entirely costal. The thighs were flexed, the hands and feet were cold. The abdomen was evenly, but not excessively distended; it was rigid and tender, and did not move with respiration. The operation was performed at the end of the fourth day of the attack. Long median incision. A seropurulent exudate flowed out. The peritoneum was intensely injected. The left side was explored first. In the left lumbar region there was an area of intestine thickly coated with fibrin, showing that the pus had reached the left side at an early stage of his attack. In the region of the appendix a large amount of pus was evacuated. The appendix was covered with omen-

tum; its tip was gangrenous, and the omentum overlying it contained a small abscess. The appendix was removed and its stump charred. The intestine in that region was covered with a layer of fibrin, which extended along the ascending colon to the liver. Here another collection of pus was found, and again another welled up from behind the gall-bladder. Lavage with saline solution. Through-and-through silk sutures. No drainage. The pulse was very poor after the operation. A hypodermoclysis was given, followed by an intravenous infusion. The patient's abdominal pain continued after the operation; his temperature continued to rise up to 106.7° on the day following the operation, when he died. The progress of his sepsis was not interrupted at all by the operation.

A perusal of this report of cases will, on the one hand, give us pleasure through the knowledge that so much can be done for them; but, on the other hand, will cause us to regret that a small number of patients could not be saved. Careful reflection will doubtlessly lead us to the conclusion that, while improved methods of treatment will enable us to save many cases that were formerly beyond our therapeutic ability, yet there are other cases where the general systemic affection has progressed to such a stage that the removal of the infectious material from the peritoneal cavity cannot save them, no matter to what degree of perfection the method of operation has been elaborated. The only advice to be given in regard to these is, not to let them run till they have reached a dangerous stage, but to operate as soon as the diagnosis has been made.

HOSPITALS CONNECTED WITH MEDICAL SCHOOLS.

By D. B. St. JOHN ROOSA, M.D. LL.D.,

NEW YORK.

PRESIDENT OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

A RECENT article in the MEDICAL RECORD,* "Hospital Reform in a New Light," has led me to believe that there is a very great misunderstanding in some minds—I hope not in many—with reference to the preeminent usefulness of hospitals connected with medical schools. The writer of the article in question says what is entirely true, when he remarks that "such institutions are to all intents not primarily places for the healing of the sick, but are subsidiary instruments for medical education and clinical instruction," but, to my mind, he is quite incorrect when he proceeds to say that "of necessity such hospitals must first consult the interests of the student-body rather than that of the indigent sick." It is the contention of those who maintain hospitals for teaching purposes, that the interests of the patient and of the student observing the cases with the teachers, are one and the same, that no kind of antagonism exists between them, and that the hospitals are the very best for the sick that can possibly be organized and maintained. It is almost impossible that any continued abuse, such as maltreatment or neglect, or any unkindness, would be allowed to obtain in a teaching hospital for it is under the supervision, not only of the physicians in charge, but also of the doctors and students of medicine who frequent its wards. It would be a great slander upon the physicians and surgeons who attend such hospitals to intimate that there is anything in their service which necessarily sacrifices the interests of the patient for those of the student. It is impossible that any interest of the student could be favored by anything that could be harmful to the patient, even as to the matter of being examined before a class. That very thing of itself insures, if it is necessary to insure any such thing on the part of the physician, kindly treatment, for no body of students or practitioners would ever submit for any length of time, or for repeated times, to see patients abused by physicians who were exhibiting them. The writer of whose article I am speaking may suppose that such hospitals favor commercialism, rather than humanitarianism, but this is an incorrect conception of the character and conduct of those who attend such hospitals. The man whose scientific bent of mind causes him to devote a large portion of time to the medical care of the poor, knows perfectly well that high appreciation on the part of his fellow members of the profession, and a more or less enduring fame and a gradual increase in his private practice, are what he may obtain—the former directly, the latter indirectly—from such work. The history of attending physicians and surgeons of teaching hospitals in this country, of which there are not enough, shows that in all the characteristics of a high standard in ethics, and in their general reputation for liberality and tenderness of heart, they are not inferior to their brother practitioners. There is nothing in their devotion to their clinics that necessarily fosters mercenary or commercial feelings. The general practitioners of the country, those not expert in particular departments, give them their confidence to a degree that shows that the profession as a class thinks very highly of them.

What goes on in Germany, France, and Austria, where all the hospitals are teaching hospitals, where all the hospitals are taken care of by the municipality or the general government, does not show any predominance of the commercial spirit in the profession. The State of Pennsylvania gives an annual and generous donation to each of the hospitals connected with medical schools of the city of Philadelphia. I have never heard that the profession in general in that city, has ever objected to such a gift on the part of the State. Hospitals connected with medical schools will be found to advance the interests of the State there as everywhere else. It is to these great cities that the earnest students of our time and the years preceding us have gone for clinical instruction, without which a rational practice of medicine is scarcely possible. The writer of the article I am reviewing claims that in these teaching hospitals the poor are not treated from purely charitable motives, but as a matter of gain and aggrandizement. It is a principle in law that no man's motives can properly be questioned so long as his action is correct. No argument would be listened to for a moment in any court in our country, where it was admitted that the action complained of was of itself beneficial and meritorious. Our writer must admit that, whether the attending surgeons or physicians of hospitals connected with medical schools are or are not actuated by charitable motives, they are quite as likely to be as men who attend hospitals where students are not admitted. We do not suppose that the presence or the absence of students has anything to do with the charity of the professional attendance.

It is true, as the writer whose paper we are criticising states, that "for a number of years, whenever the city's budget was made up, the connected hospitals with medical schools found it

*MEDICAL RECORD, October 27, 1906.

necessary to have representatives appear before the Board of Estimate and Apportionment to oppose the sentiment against their securing a share of the city's bounty." The men who opposed the legal and humane appropriation of money to aid in the support of indigent hospitals were not successful in their efforts. The city authorities considered the opposition to these payments as not being well founded, and the payments continued to be made, although modified as to method of payment, from that of a lump sum to a per diem allowance for absolutely poor patients treated. To this extent, therefore, the writer's contentions have not been agreed with.

From the general trend of the paper which I am reviewing, it would be supposed that the attending physicians of hospitals attached to colleges were directly making large salaries and contributing nothing towards the maintenance of the institutions where they teach. The history in this new country of such institutions, shows that the most charitable men in the profession are those who not only give their services to the poor, but who, as in some institutions, at least, give their services in lecturing absolutely without fee, and also contribute to the maintenance of the institution by individual subscriptions. The medical colleges, under-graduate and post-graduate of America, have never been able, as in many foreign countries, to fall back on the government for their foundation and establishment, but there have never been wanting those in the olden time, and in the present, in this city, in Boston, in Philadelphia, in Chicago, and in other large cities of the country, to devote not only their time but also their money to the upholding of a high standard of medical education. That this reacts to the advantage of the community at large scarcely anyone would deny. Were the hospitals connected with medical schools abolished in New York City, New York would no longer attract men to study medicine or to enlarge their experience as practitioners; the profession would then assume a position of practising medicine solely for gain and for experience to be devoted to private patients. It is hardly to be supposed that the State would welcome any such change.

When the last Constitution of the State of New York was created, as I have before stated in writing on this subject, the Honorable Joseph H. Choate, who is generally conceded to be the head of the Bar in New York, who was a prominent member of this body, and who is, besides this, personally interested in the care of some of the charities of the city, stated in one of the speeches that he made before the Constitutional Convention, that the State of New York recognized two kinds of charitable institutions, one in which the whole support was derived from the State, the other in which the State—and he meant by State the city or State government—provided a portion of the funds necessary, the larger amount being furnished by the public who were interested in the welfare of the institution. The oldest hospital in this city, the New York Hospital, has always been a teaching hospital, its amphitheaters have always been open to practitioners of medicine to witness its operations and to hear its lectures. Its physicians and surgeons have generally been teachers in the medical colleges of New York. It was subsidized by the Colonial government under which it was founded, and this subsidy was maintained by the State of New York until 1856. Besides this, sailors who paid hospital money from their wages to the United States were taken care of in the institution for this money. Has the New York Hospital been any the less a philanthropic institution because it has been a teaching hospital? Valentine Mott, Kearney Rogers, Gurdon Buck, Alfred C. Post, Willard Parker, William H. Van Buren, in surgery, and Alexander Hosack, Joseph M. Smith, Thomas Cock, and Henry D. Bulkley, in medicine, regularly gave instruction to medical students and practitioners, and acquired renown, which accrues not only to their memory, but to the glory of New York City. At one time the University Medical College of this city received an annual subsidy; at another time Bellevue Hospital Medical College was upon land leased to it by the city for a moderate sum. It seems to the present writer that these things are to be commended, and not to be made a source of reflection upon the members of the profession who are teachers in hospitals connected with medical schools. I am perfectly well aware of the style of argument that has been used in the Board of Estimate and Apportionment against giving money to hospitals, because they were connected with colleges, and I have not failed to be present and to answer our accusers. The suffering poor of this city, whether properly or improperly, whether rightly or wrongly, know that they are tenderly treated in the hospitals connected with medical schools, and cheerfully enter them. It will be a bad day for the charity of New York and Philadelphia, as well as for their medical renown and usefulness diffused over the whole nation, if hospitals connected with medical schools do not continue to receive the support of the intelligent and charitable givers of our city, as well as aid from the city or State. We who are active in maintaining them will never apologize for our efforts to convince both sources of our worthiness. We are of much more service to the community and the Government than they are to us.

MORE ETHER; LESS CHLOROFORM.*

By JOSEPH E. LUMBARD, M.D.,
NEW YORK,
ANESTHETIST TO THE HARLEM HOSPITAL

THERE are few subjects to which a medical student gives less attention than that of anesthetics. Sir Frederick Treves said: "There is a widespread impression that to give chloroform is a minor act; the power comes with the diploma, and the significance is sometimes emphasized by the remark: 'Well, if a man cannot give chloroform, what can he do?'"

Ether and chloroform are still our chief anesthetics, and have been rivals for the surgeon's favor for more than half a century. Ether is often preceded by nitrous oxide or ethyl chloride, either of which renders the administration shorter, safer, and pleasanter.

Contrast the old way of strangling the patient into insensibility by the cone method, with practically no air, and that of using gas or ethyl chloride as a preliminary, and the patient knowing nothing of taking ether. A medical friend who had experienced both ways said he knew of no more striking illustration of hell and heaven than taking ether by the two methods mentioned.

Nitrous oxide is the safest and most agreeable anesthetic and it is by far too little understood and used. This is, perhaps, natural, as our medical colleges teach too little about it. Furthermore, it is not always easy to obtain, and the instrument for its proper administration is quite expensive.

*Read before the meeting of the Harlem Medical Association, October 3, 1906.

I highly recommend it for simple operations, or those of short duration, or for painful examinations and dressings. It is not contraindicated when heart or lung disease is present, but it should not be employed in cases with arterial degeneration or with aneurysm. In young children under the age of five years ether is preferable. Its most important use in surgery at the present time is as a preliminary to ether. Given in this way, it greatly lessens the patient's suffering and is a time saving measure.

Ethyl chloride has been favorably known for many years as a local anesthetic, but for the past few years it has been used as a general anesthetic, and in many localities it is trying to displace nitrous oxide in general surgery, especially as a preliminary to ether. The inhalers for its administration are too numerous to mention.

For short operations, needing more prolonged and deeper narcosis than is usually obtained by nitrous oxide, ethyl chloride is of advantage. It is also better for children than nitrous oxide. It should not be used in cases where there is much thickening of the tissues of the neck, as in laryngitis. Its use is also contraindicated in neurotic and alcoholic patients. Although ethyl chloride is cheap and easy to carry around and administer, we should not lose sight of the most important fact that it is not as safe as nitrous oxide. Thos. D. Luke, Edinburgh, in the *Lancet*, May, 1906, reports 22 deaths, and W. J. McCardie, *British Medical Journal*, March 17, 1906, reports 38 deaths from its use.

For practical purposes we might say that ethyl chloride is to nitrous oxide as chloroform is to ether.

Other anesthetics and drugs sometimes used in combination with ether and chloroform are: Scopolamine, somnoform, morphine, and atropine. Scopolamine is usually given in doses of from 1-150 to 1-100 gr., combined with 1-8 to 1-4 gr. of morphine in from one to three doses, administered from one-half to one and one-half hours before the operation, preferably in divided doses. The long and disagreeable after-effects and the numerous deaths reported from its use will prevent the drug from becoming popular, although many French and German anesthetists continue to use it without hesitation and with reported good success.

Somnoform is merely a mechanical mixture of ethyl chloride (60 per cent.), methyl chloride (35 per cent.), and ethyl bromide (5 per cent.). It is more expensive, leaves a very disagreeable odor, and has an unpleasant effect upon the patient. It is not considered as safe as pure ethyl chloride.

A hypodermic injection of morphine from 1-8 to 1-4 gr., with or without atropine sulphate 1-150 to 1-100 gr., is often given from twenty to thirty minutes before operation in alcoholics and athletes.

Atropine is often used hypodermically in cases where the mucous secretions are excessive along the respiratory tract; also to stimulate the heart.

Ether.—As the usual modes of administering ether are well understood, I will refer only to two that are of value, but not generally recognized—namely, the drop method, and ether narcosis obtained by giving warm ether vapor per rectum.

The drop method should begin slowly, as with chloroform. The most simple and, to my mind, one of the best ways of giving it is by the open, continuous method, after the so-called surgical stage has been attained by gas-ether with the Bennett inhaler. Many fail in this method because they use too small a mask, or do not constantly drop the ether. A mask is used similar to the Esmarch, but larger, and is covered with two thicknesses of stockinette; the ether is dropped constantly, from 120 to 150 drops per minute, until the face flushes or the patient feels drowsy; then extra gauze is applied and the ether continued until the patient is well under its influence; the extra gauze is then removed and the ether continued as before. This simple and safe method has much to recommend it. The patient's breathing and appearance are more natural than under any other method of anesthesia, his recovery is rapid, and disagreeable after-effects are usually absent.

This method is highly recommended for children and old people. Miss Alice Magaw, anesthetist to Drs. Charles and William Mayo of Rochester, Minn., has used it exclusively in over 14,000 cases without any deaths or serious results. Even the struggling and feeling of strangulation rarely occur by this method. For a dropper I recommend a wick made of gauze or cotton, and placed alongside the cork in the original ether can. It is simple and convenient and always easy to obtain.

Rectal etherization was first attempted by Dr. Pirogoff in 1847. Drs. Robert F. Weir and William T. Bull tried it in several cases in 1884, but with only partial success. Drs. John H. Cunningham and F. H. Lehay of Boston, Mass., have obtained most excellent results with this method and have a record of over one hundred cases. The first important preliminary to this method is that the patient must be on a low diet for two or three days before the operation. A saturated solution of magnesium sulphate, two ounces, should be given twice before the operation. Sufficient time should elapse between the doses, so that the effects of one may be obtained before the other is given. As many enemata should be given as are necessary to make the rectum clean. Breakfast before the operation should consist of two ounces of beef tea. The rectum must be entirely emptied of all liquids and gases. A bottle with a capacity of 34 ounces, containing 29 ounces of ether, is placed in a bath of warm water of from 80° to 90° F. A rectal tube is then introduced from ten to fourteen inches and the warm ether vapor is pumped into the rectum until the patient is well narcotized. The apparatus resembles the Junker inhaler, except that the bottle is larger and the outgoing tube connects with the rectal tube. Two or three compressions of the bulb per minute will usually suffice. This method affords the surgeon a free field in operations upon the head, face, mouth, nose, throat, ear, and neck, and is also of value in patients suffering from lung trouble. The absence of the ether inhaler in operating on the head, face, and neck not only lessens the technical difficulties of the operator, but also the chances for sepsis. The patient is easily affected, there is no sense of suffocation, less ether is used, the stage of excitement is absent, and recovery is more rapid and less disagreeable. Patients who have taken ether by inhalation and per rectum prefer the latter method. There are no disadvantages, excepting in some cases a few colicky pains.

Another advantage of this method is that the rectal administration of ether takes the place of chloroform, which has always been used almost exclusively for head surgery. Ether is safer, and the anesthetist is out of the surgeon's way.

The objections to ether are its irritability to the air passages, the nausea and vomiting, and the cerebral excitement. Ether, as is well known, is inflammable, but if used below the level of the artificial light there is practically no danger. Another objection is the possibility of causing ether pneumonia. These are all minimized by the preliminary use of nitrous oxide, and by the drop method; also by the rectal method. Washing out the stomach

after giving ether greatly lessens, and oftentimes completely does away with, postoperative vomiting. The lavage should be immediately after the operation, before the patient regains consciousness. The drop method will greatly lessen the possibility of pneumonia, and I have never heard of its occurring in cases of narcotization by the rectal route. Ether pneumonia is claimed to be caused by the anesthetist and not by the anesthetic.

The advantages of ether are: (1) The first and all important advantage is its safety. (2) It is stimulating, whereas chloroform is depressing. This can well be demonstrated when you have a flagging pulse under chloroform, and change to ether. (3) Ether will stand more abuse than chloroform, which is a great advantage when one is obliged to have a novice administer the anesthetic. (4) Ether usually gives warning of approaching danger, which chloroform seldom does. (5) The practical working range of ether is much wider and there is less fear of accident from an overdose than when chloroform is used.

In this connection it may be said that more than 65,000 persons have been etherized at the Massachusetts General Hospital and the Boston City Hospital, and as far as can be ascertained there has not been a single death due solely to the anesthetic. (See G. W. Gay, International Textbook of Surgery, p. 421.) In New York City, according to the records of the Board of Health, communicated to me officially by Chas. J. Burke, M. D., the Assistant Registrar, from 1901 to 1905 the deaths from chloroform numbered 40; from ether 21. Considering the immensely larger number of etherizations, this shows very forcibly how much safer ether is as an anesthetic.

The contraindications of ether are: (1) Protracted operations about the mouth, jaw, nose, and pharynx. The contraindications in these cases can be overcome by the rectal method. (2) All operations requiring the use of the actual cautery. (3) Any acute pulmonary irritation, or advanced or acute renal disease. However, the use of ether cannot be excluded by any hard and fast rule.

Chloroform.—When chloroform is given by the open mask method the patient should always have plenty of air. Our English friends go as far as to say that the mask never should touch the face. The Junker inhaler is often used in head surgery. Its principal advantage is that the vapor is pumped through a tube through the mouth or nose. Chloroform is not inflammable, and were it not for its dangers it would be an almost ideal anesthetic. Chemically, it is very sensitive. Light plus air may change it. It should be used from the original bottle. Dust will change chloroform, but not ether.

Chloroform should be administered very gradually; pushing it is dangerous, and it is here that the accidents attending its use are most frequent. The patient is restless; the surgeon is ready to operate; the anesthetist, perhaps a junior, without proper training or experience, fearing the displeasure of the surgeon, pushes the chloroform; in fact, oftentimes he is told to do so; the patient breathes deeply and you get the toxic effects of the drug and sometimes a fatal issue. Most deaths from chloroform have occurred during the first few minutes of its administration, and this is one reason why it should not be used for the removal of adenoids or other short operations, as is commonly done.

The advantages of chloroform are that it has an agreeable odor; it is less irritant to the air passages than ether; it is less apt to cause nausea and vomiting; it occupies less space, which is an advantage in the army and navy service, and it is not so expensive to buy or administer.

Its one great disadvantage, which overshadows all the points in its favor, is the danger attending its use. In spite of this, it will always be the leading anesthetic in warm countries, as ether boils at 96° F., and is not practical for use excepting by the closed method in such climates.

Chloroform is usually preferred in patients with renal or pulmonary disease, in brain surgery, and in tracheotomy. Probably its greatest field of usefulness is in obstetrics. Here the element of fear, which has been so well described by Dr. John Bodine,* is practically *nil*, as the patient welcomes anything that will put an end to her labor pains.

When chloroform is indicated, care and proper management in its administration greatly lessen its dangers. It is contraindicated in cases of fatty heart, in lymphatic conditions, and in adenoids.

Chloroform certainly has its field of usefulness, but I think it is often used where ether could and should be more safely substituted. This is especially true in the two very common operations for adenoids of the pharynx and curettage of the uterus. Dr. T. D. Luke reports 30 deaths from 1897 to 1903 from chloroform administered for adenoid operations.

Comparative merits of ether and chloroform.—Ether is slower in its effect, less pleasant to inhale, more bulky, and more expensive; it is inflammable, sometimes irritating to the air passages, and is often followed by nausea and vomiting; however, it usually gives warning of danger, and is safe under ordinary circumstances.

On the other hand, chloroform is quicker in its effect, pleasant to take, less irritating to the mucous membrane, less bulky and less expensive; it is not explosive, and usually causes less nausea and vomiting; it does not always give warning of danger, and is not always safe.

The merits of each case must be carefully considered when selecting the anesthetic, and neither chloroform nor ether should be used exclusively. Ether, however, being the safer, should always have the preference when it is not contraindicated. After all is said, it is experience that counts more than the anesthetic, or the apparatus that is used.

In order to ascertain the views of one hundred surgeons throughout the United States, I sent to each one a letter, of which the following is a copy:

August 18, 1906.

Dear Doctor:—

I am endeavoring to ascertain the relative favor in which ether and chloroform are now held by the general surgeons in this country, and with that purpose in view I have taken the liberty of sending you, among others, a copy of the following list of questions. The replies to these will be embodied in a paper on "More Ether; Less Chloroform," which I expect to read before the Harlem Medical Association of New York on October 3, 1906.

1. Which anesthetic do you prefer in general surgical work? (a) Ether? (b) Chloroform?

2. Which method of administration?

3. As preliminary to the use of ether, do you prefer (a) Nitrous oxide? (b) Ethyl chloride?

4. In your opinion, do you think anesthetics and their method of administration receive proper attention in the curriculum of our medical colleges?

5. How many deaths have come under your ob-

*International Clinics, Vol. III, Twelfth Series.

servation from the administration of (a) Ether? (b) Chloroform?

Thanking you in advance for your courtesy, I am

Yours very truly,

Seventy nine answers were received from the following surgeons in twenty-three States: Robert Abbe, W. S. Bainbridge, Carl Beck, J. A. Blake, J. A. Bodine, G. E. Brewer, Leroy Broun, J. D. Bryant, W. B. De Garmo, H. B. Delatour, C. N. Dowd, Ellsworth Eliot, Jr., C. A. Elsburg, J. F. Erdmann, R. Guiteras, Frank Hartley, H. A. Haubold, I. S. Haynes, J. W. Hearn, J. J. Higgins, L. W. Hotchkiss, L. J. Ladinski, W. G. Le Boutillier, H. Lilienthal, S. Lloyd, W. H. Luckett, Willy Meyer, Robert T. Morris, A. V. Moschcowitz, L. S. Pilcher, J. D. Rushmore, H. Roth, Parker Syms, M. W. Ware, Joseph Wiener, Jr., Robert F. Weir, and J. A. Wyeth, New York; Lewis L. Basher and Stuart McGuire, Richmond, Va.; F. E. Butts and G. W. Crile, Cleveland; A. E. Cabot, D. W. Cheever, G. W. Gay, F. W. Harrington, M. H. Richardson, and J C. Warren, Boston; William H. Carmalt, New Haven; John B. Deaver, Richard H. Harte, J. W. Hearn, and Edward Martin, Philadelphia; W. H. Doughty, Augusta, Ga.; Duncan Eve, Nashville; Leonard Freeman and C. A. Powers, Denver; F. N. Gerrish and Seth Chase Gordon, Portland, Me.; John M. Gile, Hanover, N. H.; W. S. Halsted, Baltimore; Thomas W. Huntington, San Francisco; Edward J. Ill, Newark, N.J.; Robert W. Johnson and Howard A. Kelly, Baltimore; A. F. Jones, Omaha; W. McD. Martin, Mobile; Archibald MacLaren, St. Paul; Chas. H. Mayo and Wm. J. Mayo, Rochester, Minn.; John B. Murphy, A. J. Ochsner, and N. Senn, Chicago; Roswell Park, Buffalo; H. H. Mudd, St. Louis; Manning Simons, Charleston, S. C.; F. D. Smyth, Memphis; Bacon Saunders, Ft. Worth, Texas; H. C. Tinkham, Burlington, Vt.; A. Vander Veer, Albany, N. Y.; G. E. Vaughan, Washington, D. C.

The following is a summary of the answers received:

Question 1. Sixty-seven preferred ether; 7 chloroform; 1 anesthol; 4 were noncommital.

Question 2. In the case of ether, 38 used the drop method; 16 the Bennett inhaler; 11 the cone; 8 the Allis inhaler; 1 the Blake inhaler. If chloroform were used, 11 preferred the drop method, 1 the vapor method.

Question 3. Forty-eight nitrous oxide; 3 ethyl chloride; 3 morphine hypodermically; 1 morphine and scopolamine hypodermically; 1 A.-C.-E. mixture; 1 anesthol occasionally; 20 nothing or noncommittal.

Question 4. Sixty-eight answered in the negative.

Question 5. Ether, 53 deaths; chloroform, 91 deaths.

The answers to these questions are most interesting and of very great importance. They show that there has come to be an almost universal consensus of opinion in favor of ether, excepting under very special circumstances. Considering that chloroform is so much easier of administration and has less inconveniences, this is a very striking tribute to the safety of ether. The collected statistics show that a revolution has been effected in this matter in the last twenty-five years. While there used to be many men who preferred chloroform, now these are but few. Of all who have answered the question directly, 67 prefer ether, 7 prefer chloroform, 1 anesthol, and 4 are not committal.

The question of a preliminary to the use of ether now interests every surgeon without exception. A few years ago no one thought of the strangling of the patient; now everyone considers this sufficient to justify going to considerable expense and trouble in order to prevent it. Within the next five years no one will think of administering ether without having some method of preliminary narcosis. This is a decided humanitarian advance.

All are agreed that enough attention is not paid to the teaching of the administration of anesthetics in our medical schools. I should not say all, because there are a few men who consider that sufficient attention is paid to the subject under their own supervision. They only serve to emphasize the fact that personal care in the training of anesthetists is needed if they are to be capable of assuming this important duty. His diploma alone justifies no man in giving an anesthetic unless he has had considerable experience.

Some of the expressions of opinion in this matter are so strong that I have felt that I am justified in quoting them. Dr. Robert Abbe says: "Judging by the flower of the graduates after passing examinations and entering hospital service, they show dangerous ignorance." Dr. Joseph D. Bryant says: "No, nor in hospitals, either." Dr. Joseph B. Higgins says: "Students know absolutely nothing about it." Dr. J. B. Murphy says: "I not only never had a death, but never saw one. In Mercy Hospital, where I do most of my operating, the ether is administered entirely by a Sister of the Order of Mercy. Occasionally I use a Bennett evaporator in the Presbyterian Hospital. There the work is in charge of a physician who makes a specialty of anesthetics. I very much prefer, however, to have a woman, and preferably not a physician.

Of course, I did not expect very frank confessions with regard to the number of deaths that take place and have taken place from various anesthetics. The declaration of Dr. Luke that chloroform maintains its popularity among physicians in Scotland, because there are no coroner's inquests, is extremely interesting and suggestive. The answers to this question show that both ether and chloroform have their dangers, unless properly and very carefully administered.

Conclusions.—(1) Ether is more generally used than chloroform, because it is safer.

(2) The drop method of administering ether is very popular.

(3) Nitrous oxide is preferred as a preliminary to ether by nearly all who have used it under favorable circumstances.

(4) Medical colleges do not place enough importance upon anesthetics and their administration.

(5) If more ether and less chloroform were used, we certainly would have fewer deaths.

1025 Seventh Avenue. (Graham Court.)

Bisulphide of Carbon in Fibrinous Pneumonia.—Luigi Masciangioli says that bisulphide of carbon, when administered internally in fibrinous pneumonia, is absorbed into the blood and acts on the germs of pneumonia, destroying their vitality and neutralizing the toxic products so as to limit the progress of the disease. It is the antiseptic action of the drug through the blood that cures, and it seems to have an elective action on the germs which produce the disease. He describes a number of cases treated with this drug in which it seemed to limit the disease very quickly and recovery was more rapid than is usual in such cases. The temperature fell on the third or fourth day of the disease, and the symptoms all disappeared rapidly. The fall of temperature occurred while hepatization was in progress and the expectoration was very scanty.—*La Riforma Medica.*

AN IMPORTANT FACTOR IN THE CAUSATION AND TREATMENT OF MANY SO-CALLED FUNCTIONAL DISORDERS*.

By CARL G. LEO-WOLF, M.D.,

NIAGARA FALLS, N. Y.

Before I start on my paper I beg to remind you that I am not a specialist, but a general practitioner, one who is interested in his work in all its phases and who believes in accepting of the work of others what he thinks meritorious and of benefit to his patients, and who considers himself qualified to make observations of his own and to draw the proper deductions therefrom.

You all know that under the term "functional disorders" we comprise a large number of disturbances in the different organs of the body which we are able to recognize only by the altered function of the particular organ and the concomitant malaise, but into the causation of which pathological anatomy has, so far at least, failed to give us any insight.

We have been accustomed to accept various theories as to the causation of some of these functional disorders and have naturally been disappointed more than once when the exceptions to these theories formed the rule rather than proved the rule.

During the last decade or two a new factor has come to be recognized by some of us in the causation of many of these disorders, and this is "eyestrain." We have been charged with exaggeration and with juggling our records to fit our "pet theory" as it pleases some to call it, though in my opinion it is long past the theoretical stage, and is now a dogma as well established as that certain bacteria will, under proper conditions, produce certain infectious diseases.

Up to now our treatment of functional disorders had to be symptomatic, and in consequence thereof more or less disappointing. But if, as is claimed by us believers in the far-reaching effects of eyestrain, we have found an etiological factor which can cause some of these disorders in even a small percentage of cases, should we not as scientific men endeavor to find these few cases, which can be done easily and without any discomfort to the patient; and should we not sooner give every one of these sufferers the benefit of a doubt before we condemn them to symptomatic treatment, which means many times nothing less than lifelong dieting and drugging and partial or total invalidism?

I shall not go into any more or less learned dissertation about the connection between the eyes and the rest of the body, but I shall leave this part to the physiologist and pathologist, as a general practitioner, I shall now proceed to enumerate to you those functional disorders which I believe to be caused at times by eyestrain and have myself seen to be in some instances directly traceable to it.

Starting with the nervous apparatus, we have first of all those headaches of obscure origin which are still frequently referred to autointoxication, for want of another term more occult or indefinite; it was in these headaches that the etiological factor of eyestrain was first recognized and so universally accepted that many of these patients now consult the oculist or optician without the advice of their physician; but unfortunately this has left the impression on the minds of laymen as well as of many physicians, that these headaches are the only symptom of eyestrain, and frequently I have had a patient say, when I advised him to consult an oculist for some other condition, "Why should I see an eyedoctor and wear glasses when I have never had a headache in my life?" That exasperating condition, both to patient and physician, migraine, blind or sick headache, is in my experience usually caused by eyestrain, and I have still to see the first case of migraine with emmetropia.

Hysteria, this lucus a non lucendo, which is still so named, though we know now that it is hardly ever caused by uterine disease, and simply because we have not taken the trouble to find a better name for it, I have seen repeatedly caused by eyestrain and cured it completely in a short time by combining our usual methods of treatment with those of the refracting oculist.

The same I can say about neurasthenia, which is a disorder of men with sedentary habits and of nervous prostration, which we find usually in women with too much money and leisure hours spent in reading novels in a reclining position; I have not yet seen a case of nervous prostration in a washerwoman nor of neurasthenia in a track-hand.

We have lately accepted the theory that chorea is caused by the same microorganism as acute inflammatory rheumatism, and undoubtedly this is true in quite a number of these cases; but where we cannot find any valvular affection of the heart nor a history of acute arthritis, we will do well to have the eyes refracted, as was shown to me only lately in the case of a girl of ten, who had been treated by others for chorea for the last two years and who has been cured of her choreatic movements through glasses and simple tonics.

Neuralgia, especially that of the trigeminus, I have seen due to eyestrain. Do you not think it advisable to have such a patient's eyes examined before we tell him to submit to an operation like the excision of the ganglion Gasseri, even if we should find only one case in a thousand whom the wearing of glasses will relieve?

To come to the respiratory organs, we find in the nasopharynx frequently recurring "colds" to be due often to eyestrain; one of my friends gets a "cold" whenever the frames of his glasses for compound astigmatism are bent. All physicians know that looking into strong light may cause sneezing, but few will acknowledge that there could be any connection between ametropia and nasopharyngeal catarrh. I have also cured a number of cases of dry hacking cough, accompanied by no local or other symptoms, with the help of the oculist.

Nowadays I do not attempt to undertake the treatment of an asthmatic patient without insisting on their submitting to refraction, as I believe to have proven to my own satisfaction the existence of an occasional ocular origin of asthma.

We would hardly expect to find any effect from eyestrain on the vascular system, and yet I have seen idiopathic arythmia cordis, as well as tachycardia, from this cause. Angio spasms or cramps in the extremities are also a frequent symptom of eyestrain.

That most frequent form of anemia, usually occurring in girls at puberty, which is always combined with obstinate constipation, "chlorosis," is quite amenable to treatment after the proper glasses have been prescribed, and all its symptoms, including the constipation, disappear in a short time. Constipation, with or without chlorosis, is in my opinion frequently coincident with and dependent upon eyestrain, and I have in quite a number of cases re-

*Read before the Section of Medicine of the Buffalo Academy of Medicine, October 9, 1906.

lieved my patients from this disorder with glasses and thereby emancipated them from the habitual use of drugs and enemata. Mucous colitis I regard as a nervous disorder of the intestine due to eyestrain and the constipation caused by it.

By far the most frequent functional disorders, and those which are in quite a number of instances caused by eyestrain are those of the digestive tract, which we combine under the names of biliousness, dyspepsia, nervous or otherwise; indigestion, and the different kinds of perverse chemism of the gastric or intestinal glands. Some, but only a comparatively small number, of our stomach specialists, have been quick to accept this dogma and send their patients to the oculist to perfect the diagnosis and to determine part of the therapy; but unfortunately hardly any of the writers of textbooks on digestive disorders have acknowledged this important effect of eyestrain and continue to ignore the results of the experience of their more farsighted brothers.

Of the disturbances of the urinary organs I have seen a number of cases of polyuria and dysuria in which examination revealed nothing abnormal in the chemical composition of the urine nor any local cause, which cases I have relieved with the aid of the oculist. I can say the same about some of the functional disorders of the female genital organs, such as dysmenorrhea and backache, the bearing-down sensations and heaviness, the congestions of the uterus and adnexa without any apparent anatomical cause, and the so-called disorders of the menopause.

To mention finally some disorders of the trunk, we can surely recognize a nontraumatic noncongenital form of torticollis, which is plainly functional and due entirely to eyestrain in one eye or irregular compound astigmatism prevailing in one eye. The orthopedic surgeon will also be forced to acknowledge that eyestrain is a frequent if not constant factor in the production of lateral curvature of the spine and that the treatment is refractive in these cases rather than reductive. How it would please my teacher, the late Professor Julius Wolff of Berlin, to hear of this new evidence of the correctness of his "law of the transformation of the bones," for the recognition of which he had to fight for years, just as the adherents of the ocular causation of lateral curvature of the spine have to fight now, and from present indications will have to keep on fighting for recognition for some years to come, with the ultimate result of being proven to be in the right.

These are some of the functional disorders which I have personally seen to be caused by eyestrain and which I have cured or at least improved with the aid of the refracting oculist. As to the still quite frequent failures to cure these disorders by glasses, these may be due:

First to the fact that they are by no means always caused by eyestrain; but the only means we have to find out those which are is to have the eyes of every patient of this class examined.

Or they are due to the oculist. Good ophthalmic surgeons are not always good refractionists; some are too busy to spend the necessary time, others have theories of their own and will not listen to the opinion of the general practitioner; also they are very rarely aware of their failures, except in so far as they see the failures of their confrères, though, I am convinced, without realizing that others will see just as many failures of their own.

Further, many oculists who do the best of refraction work have poor results because they do not realize that it is not sufficient to prescribe the right glasses, but that it is their duty to see to it that the glasses are fitted right and therefore leave the choice of an optician to the patient or do the fitting themselves. I have found that the fitting of glasses is an art, mastered by a small number of opticians only, and one that requires considerable time in each case and frequent control. I have also not yet found an oculist who is a good fitter of glasses. I therefore advise that the oculist insist on the patients going to the one optician whom he knows to be an adept in the fitting of glasses, and I am sure that he will greatly improve the result of his work.

Finally, they may be due to the patient himself. Often the patient will object to the wearing of glasses, though I think that with a little tact and persuasion this objection can usually be easily overcome, especially in women, when you tell them, truthfully at that, that the wearing of glasses will postpone or even cure wrinkles on the forehead. Or the patient will not believe his physician, sometimes because he has already consulted some eminent oculist who does not believe in eyestrain and who has told him either that his refractive error is so small that it does not need correction with glasses, or that his eyes are all right and that the trouble is somewhere else, autointoxication, for instance, which diagnosis I have frequently met with covering poor refraction work.

The patient also many times dreads the expense of going to the oculist, and I must confess that sometimes the charges of the oculist do seem rather high in proportion to the patient's income, especially so when the oculist sees fit to have the patient come to him several times weekly for so-called treatments, about the nature of which I have so far not been able to obtain much light, nor have I been able to convince myself that they might be of any use in refractive errors. The consequence of this is that many patients will go to the optician, who claims to be able to examine the eyes thoroughly, and to do so free, charging for the glasses only. In this connection I would like to mention two facts which I have always failed to understand: First, how some physicians, graduates of reputable schools, men who have taken the oath of Hippocrates on the day of their graduation, can sell themselves out to the optician for weekly wages to do his refracting, and profane their profession by unethical, unscientific and incompetent work. Second, that many practitioners of medicine, who should remember from their own student days the difficulties of the physiology and pathology of the apparatus of vision, can still persist in sending patients to the refracting optician, a mere mechanic. Why do they not also send their pathological specimens for diagnosis to the maker of microscopes?

The consequence of these failures to get the right refraction for those of our patients who suffer from some functional disorder caused by eyestrain and easily cured, or at least, if of long standing, improved by the only effective remedy—correct lenses—is to drive them from one physician to the other, to have them subjected to all kinds of unnecessary cures and sometimes even operations, until the patient despairs and either settles down to a life of invalidism with or without the addiction to drugs, or joins the large ranks of the dupes of all kinds of quacks.

Quite frequently also some disorder which was functional only in the beginning will leave its imprint on the organ of predilection and will no doubt lead to anatomic-pathological conditions. In closing let me ask only this one question: Why should we not make refraction as much of a routine examination of our cases of functional disorders as the ex-

amination of the urine and stomach contents, when we are forced to acknowledge that eyestrain is an important factor in the causation of many of these disorders?

QUININE FEVER.*

By A. L. GOODMAN, M.D.,

NEW YORK.

THE perverse action of drugs offers a great field for research work, and has attracted the attention of physiologists and laboratory workers for many years. But long before the present improved methods were known, it remained the province of the general medical man to observe this peculiar effect of drugs, and that he did so is attested by the literature of the past, rich in records of observations along these lines. A pioneer in this particular branch of pharmacology in recent times is Professor L. Lewin, whose book devoted exclusively to the contrary effect of drugs is a work which every medical man should own.

For some months past I have devoted myself to a rather exhaustive search of the literature of quinine fever, and, finding so few cases reported, I believe this condition rare enough and of sufficient interest to give you a short résumé of my case and of those cited by others.

Mrs. H., fifty-five years of age, mother of six healthy children; menopause some four years ago. Heart, lungs, liver, and kidneys negative. Always in good health until two years ago, when she is said to have contracted malaria. She said she had a few attacks afterwards and took quinine each time she thought an attack was coming on. The blood was examined at that time and the malarial organism is said to have been found.

A few years after these attacks I was called to see this patient, who complained of a feeling of malaise, headache, and a pain over her spleen, which on examination I found to be enlarged and somewhat painful. From the previous history I concluded that she might be developing one of her old attacks, and ordered six decigrams of quinine sulphate to be taken once daily. I took along a specimen of her blood and her urine, both of which gave negative results on examination. Her temperature at the time of my visit (8 A. M.) was 99°F. About one o'clock that afternoon I was called to see her again, although I had not expected to visit her until the next day. She looked miserable. Her temperature was 103.2°F. Her spleen was still sensitive and enlarged; she had a very intense headache, and complained of nausea. I concluded that she was in the midst of a paroxysm and that the quinine had not been given early enough to prevent it. That evening she had a member of the family call me up on the telephone to notify me that she felt very much better. The next day she took her quinine at 7 A. M. She was feeling well, but, as she explained, "weak from yesterday's attack." At 12 o'clock she began to feel sick again. At three o'clock I called and found her temperature 102° F. All the symptoms of the day before were repeated. The spleen was still enlarged. The examination of the urine was negative. That evening she felt well and her temperature was 100° F. All these temperatures were taken in the rectum. The next morning she took her quinine at 5 o'clock. At seven o'clock her temperature was 99.7° F. At 11 A. M. she felt very miserable and her temperature was 103.2° F. The blood examination was negative. In the evening her temperature was 99° F. I could not explain the repeated rise in temperature and asked Dr. A. Jacobi to see the case with me. It is to him that I owe my knowledge of this condition. As soon as the patient was put on a mixture of ergotin and piper nigrum, her fever failed to appear, and she made an uninterrupted recovery. Why the quinine should have acted differently at this time than it did some years before, I shall endeavor to explain later on.

The first one to report this untoward effect of quinine was Samuel Hahnemann in his translation of Wm. Cullen's Materia Medica in 1790. In an annotation on page 109, he says: "For experiment's sake, I took 60 grains of cinchona bark twice daily for a few consecutive days; my feet and hands became cold, followed by a feeling of malaise, palpitation of the heart, pulse hard and rapid, a feeling of apprehension, then a beating headache, flushing of the cheeks, thirst, and all the usual symptoms of intermittent fever. These symptoms lasted two to three hours each time, and returned after each dose. I stopped the bark and I was healthy."

It is said by Wernich in Eulenburg's Real-Encyclopädie that this effect which quinine had on him was a prominent factor in the birth of his homeopathy theory, which embraced the well known "similia similibus curantur" formulated by Hippocrates and revived with great success by Paracelsus. Bretonneau, in 1833, reports a great number of cases which he himself saw. He writes that "the prodromal symptoms were ringing in the ears, deafness, and malaise, followed by chills, headache, and gradual fall of the fever, accompanied with perspiration." He calls this susceptibility an individual idiosyncrasy, but gives no further explanation. Koehler in his text-book reviews Bretonneau's case and offers as an explanation that the quinine causes an intense gastric catarrh followed by a severe enteritis, and expresses his amazement that no one has thought of this simple solution. He also states that if quinine is given for any length of time it would be difficult to differentiate between the gastric disturbance and the malaria infection.

The first one to report these cases after painstaking repeated observation and carefully prepared clinical data was Professor Salvatore Tomasselli of Catania. His first publication appeared in 1874, with a notice of seven cases. Twelve additional cases were reported in 1877. His reports are given so accurately that I will repeat one here in detail: "The quinine, when given to cure a malaria fever or to prevent the return of a paroxysm, does not produce its well known effect, but causes instead a new febrile attack, differing from the malaria paroxysm in coming on at a different hour and in presenting different symptoms. The attack appears in from one to six hours after the ingestion of the quinine. While the patient is quiet and tranquil, and apyretic, he is seized with a convulsive tremor, more or less violent, with lowering of the surface temperature of the body; not rarely there is an aversion to the quinine. After one or two hours of this primary stage, the temperature rises rapidly, sometimes reaching 105° F. The duration of the fever is proportionate to its intensity, and usually terminates in twenty-four to forty-eight hours. If no fresh intoxication takes place, the patient regains his health; but if the toxic paroxysms be repeated at short intervals by a persistence in the quinine, and if, further, the dose be increased, the patient passes rapidly into a state of collapse and death re-

*Read at a meeting of the Harlem Medical Society, November 7, 1906.

sults from cardiac paralysis. As soon as the quinine is stopped the paroxysms disappear, and are resumed when the remedy is given again." In some of the severer cases the urine contained blood and casts. In summing up his observations he states as follows: "The complex production of all these toxic phenomena is not an intimate property of the drug, but it is a special morbid fact or entity united to an occult susceptibility of some individuals, which arises from the malarial infection. Neither the abuse nor the excessive doses of quinine can be regarded as an efficient cause of the development of such an intoxication, since this may be produced by small doses. All preparations of quinine, without excluding decoctions of the bark and the dry extract, provoke the same phenomena, but not always with the same intensity in the paroxysm. A variable period of silence (from one to six hours) intervenes between the administration of the quinine and the appearance of the morbid symptoms, according to the solubility of the drug. This incompatibility (intolerance) is congenital, but kept latent by favorable organic conditions. According to Tomasselli, it is a special idiosyncrasy occasioned by the malarial infection. The rare appearance of this strange effect and its occurrence in several members of the same family confirm this idea."

Further on in his paper he says, "there are two doubts which may arise: (1) That malarial fever, independently of the action of quinine, may be transformed into a pernicious form of icterohematuric fever. (2) That the quinine, stimulating the contractibility of the spleen, may give rise to an abundant outpouring of the malaria poison into the circulation, thus causing a fever of greater intensity with the pernicious icterohematuric form."

Professor Cantani was the first to demonstrate that the spleen did not contract under the influence of quinine. These experiments were afterward confirmed by Rochefontaine.

In 1879 Professor Karamitsas of Athens published five cases, and sustained the opinions of Tomasselli against those of Leroy, De Méricourt, and Béranger. In the same year Professor Ughetti published another case. Other cases were reported by Vincenzo, Restuccia, and Galvagno.

In 1885 Herrlich, in an excellent article, gave a detailed account of a case which came under his charge at the Charité in Berlin. To any one interested in this subject, I would advise the reading of this brilliant report. Unfortunately my case occurred in private practice, thus precluding any attempt at experimentation. The advantages of observing these cases in hospital practice can readily be seen.

Herrlich explains the rise of fever in his case as due to the contracting influence of the quinine on the tissues of the spleen, and says that after the third paroxysm the spleen was half the size that it was at first. In all the cases reported, malaria existed at the time of the administration, or had existed at some previous time. In my case there was an enlarged spleen, but even to-day the same hyperplasia exists. That the contracting influence of the quinine on the spleen does not play such an important rôle in the production of the fever following its administration can, I believe, be logically explained by the fact that if the quinine were given often enough one ought to reach a point where the contraction of the spleen reaches a maximum. In a number of cases the quinine was given time and time again, and each dose always produced a new paroxysm.

When we come to study the physiology of fever, we find its phenomena divided into the thermogenic, thermotaxic, and thermolytic. The thermotaxic apparatus, located by Ott and Collmar, has its cerebral origin in the corpus striatum, Schiff's crying center, and the anterior end of the thalamus. Its fibers probably decussate about the nib of the calamus, and then run down the lateral columns. The existence of the center about the corpus striatum has been confirmed by Sachs and Arohnson, Girard, and Baginsky. The thermogenic apparatus is situated in the spinal cord. The thermolytic apparatus, or heat dissipating center, consists of the vasomotor system, sweat glands, the lungs, and the reflex action of the surface nerves on the thermotaxic or inhibitory apparatus, allowing increased or diminished heat production, according to the surrounding temperature.

The relation of the nervous system to the temperature of the body has been the subject of experimentation for many years past. The experiments of Hitzig, Leyden, Fraenkel, Colasanti, Sanderson, Pflueger, Tscheschichin, Ott, and many others have, I believe, established the fact that fever is, broadly viewed, a neurosis—mainly a disease of the nervous system.

Professors Senator, Leyden, and Wood have studied the matter by means of the calorimeter. Senator found in fever an increased heat production, which has been confirmed by Professor Wood's numerous experiments. All the proofs go to show that the phenomena of heat are dominated by the nervous system.

It seems to me, therefore, that if we are to look for an explanation for this untoward effect of quinine, it would be the most plausible thing to expect the solution of the phenomena to be due to some chemical changes in the blood acting on the heat dissipating apparatus in persons who have, or who have had, malaria. All the cases reported were patients in whom the diagnosis of malaria had been made at one time or another. Lastly, to strengthen this logical deduction, we have to think of the various exanthemata caused by the administration of the quinine preparations.

A CASE OF PERFORATION OF THE SOFT PALATE, DUE TO TERTIARY SYPHILIS; STAPHYLORRHAPHY.*

By H. FRED LANGE ZIEGEL, M.D.,

NEW YORK.

The condition to be briefly described occurred in a male, twenty-four years old, a cook by occupation, who six years previously had had a genital chancre followed in seven weeks by rather severe manifestations of secondary syphilis. These symptoms disappeared soon after antisyphilitic treatment was instituted, but unfortunately this was carried out only for three months. For the next five years the patient was in excellent health till about one month before he came under observation in May, 1905. During that month there had been sore throat, hoarseness, and difficulty in deglutition and respiration. These symptoms had gradually increased in severity until four days before the patient was first seen, when there had occurred discharge of pus through the mouth followed by some relief from the difficulty in swallowing and breathing. In spite of the increasing severity of the symptoms the patient had not sought medical aid, he being one of those robust, phlegmatic individuals who hardly know when they are sick. A careful physical examination gave no evidence of pathological changes elsewhere than in the nose and throat. Yet the patient was in a sorry plight; he could talk hardly above a whisper, respiration was impaired, and swallowing was difficult and painful. Pus issued from the left nostril and from an opening in the soft palate. This perforation was about the size of a five-cent piece, situated to the left of the median line; its edges were irregular and necrotic, and the surrounding soft tissues were red and edematous. The ulcerated areas had an indolent appearance and were not specially sensitive. Irrigation through the left nostril by means of a small catheter resulted in the evacuation through the mouth of about an ounce of thin, odorless, mucopurulent fluid containing small particles of necrotic tissue. Posterior rhinoscopy showed the superior surface of the soft palate bulging into the postnasal cavity; otherwise this method of examination, as well as anterior rhinoscopy, laryngoscopy, and digital exploration of the pharynx, gave no additional information.

There could be little doubt as to the diagnosis, which was gumma of the soft palate with subsequent degeneration, abscess formation, and rupture into the mouth.

The therapeutic plan followed was: vigorous antisyphilitic treatment constitutionally and locally, an attempt to check the spread of ulceration and to prevent the formation of cicatricial adhesions, and frequent observation of the defect in the palate with a view to its correction subsequently. As is usual in these cases, the treatment resulted in rapid improvement; breathing became free, discharge through the nose diminished, enunciation improved, the opening in the palate contracted, and the inflammatory reaction in the nasopharynx subsided. But the patient still complained of regurgitation of fluids through the nose and of mingling of the nasal and buccal contents.

After two months of the treatment outlined before, the parts appeared sufficiently healthy for attention to the permanent correction of the palatal defect. The small size of the opening—at this time probably not of greater diameter than that of a ten-cent piece—and consideration of the annoyance and discomfort that might attend the use of an obturator, seemed to indicate closure by suture. Accordingly, under cocaine anesthesia, the edges of the cleft were freshened and five sutures were passed so as to approximate the edges. No lateral incisions were made. Most of the sutures had to be repassed more deeply because of the friable condition of the tissues; and inspection in a few days showed that the two central sutures had torn through. Subsequently, however, after stimulation with silver nitrate, the opening closed completely and the patient was without symptoms.

Three months ago there appeared a pea-like prominence on the right eyeball which was diagnosed by Dr. Martin Cohen as gumma of the sclera. This has disappeared since then; and when the patient was last seen there remained no evidence of the conditions described except a linear scar at the bottom of a depression in the soft palate.

*Presented before the Harlem Medical Association, November 7, 1906.

The Modern Theory of Immunity and Endovenous Injections of Sublimate.—F. Mariani calls our attention to the possibility of vaccination with chemical substances as well as with organic substances. The author has studied the use of corrosive sublimate injected endovenously to produce an immunity both preventive and curative. After a long series of experiments he has arrived at some definite conclusions. By vaccination with small doses of sublimate introduced into the veins of man and animals we may obtain a serum that is antitoxic, bacteriolytic, and agglutinating, and there is at the same time an increase of the mononuclear leucocytes in the blood. These properties are not limited to a single germ, but act on germs of various sorts, diplococci, bacillus of Ebert, streptococcus, and bacillus of Koch: thus we have a polyvalent antitoxic serum, and animals may be vaccinated against several sorts of germs. The beneficial effects are not due to the salt of mercury, but to the complex of biological factors that constitute immunity. By this method the principles of defense that constitute immunity are brought into action against the infection. Large doses cause an intoxication of the organisms which diminishes the resistance of the body. The proper doses for man are one to five milligrams of sublimate per day. The syringe should not be completely filled with fluid when the injections are made, and a few drops of blood should be aspirated into the syringe before injecting, so as to become mixed with the solution used, which is then injected.—*Il Policlinico*.

MEDICAL RECORD.

ABDOMINAL FAT NECROSIS.

THE etiology of abdominal fat necrosis has been shrouded in uncertainty for many years, and even at the present time, despite many painstaking efforts at solving the problem, there are numerous features still to be explained. The results of the many researches seem to show that there is an intimate connection between this condition and some lesion of the pancreas—that is to say, changes in the latter may be accompanied by necrosis of the adipose tissues of the abdominal cavity. Two principal theories have been brought forward to account for this phenomenon, one of which ascribes the necrosis to a fat-splitting ferment present in the pancreatic secretion, the other to the effects of bacterial action. The latter has been quite generally abandoned, but the ferment theory has been proven by numerous investigations to have a basis in fact, and it is claimed that the necrotic process is due to the direct contact of the pancreatic secretion with the fatty tissue in the free abdominal cavity. Although this is probably true in many instances, there are others in which the peculiar localization of the necrotic area seems to point to some other etiological factor. Thus the phenomenon has been observed in the subpleural and subpericardial regions, in the subcutaneous tissues, in the spinal column, and in a number of other places.

One of the most recent investigations on this subject has been conducted by Payr and Martina (*Zeitschrift für Chirurgie*, Vol. 83, No. 1) who were tempted to seek an entirely different explanation for the necrotic process by the results obtained in their experiments with liver sutures. In attempting the latter with the aid of magnesium plates they found as one of the consequences that peculiar changes took place in the lungs, and these, on closer examination, were found to be caused by small emboli of liver cells which were due evidently to operative injuries. They were thus led to make similar experiments with the pancreas and found that crushing injuries of even a very slight degree were followed by extensive fat necroses. This pointed to embolism, and, although a condition of the kind had already been suspected by others, Payr and Martina succeeded in proving by histological methods that this actually occurred.

These embolic necroses, if they may be thus designated, are distinguished from those due to direct contact with the pancreatic secretion in a number of ways. Necrosis due to the latter appears early—within two hours—whereas the other forms require several days for their development. The localization of embolic foci of necrosis is in the neighborhood of the veins where collections of pancreatic cells may be demonstrated in microscopic section. The conditions of these animal experiments are readily enough reproduced in the human subject, in whom trauma, hemorrhage, and inflammation of the pancreas are not uncommon. It seems, therefore, that we now have another satisfactory explanation of this phenomenon, which is, moreover, of considerable practical importance, for, with a knowledge of the dangers which undue manipulation of the gland entails, greater care must be exercised in handling the organ during operations in this portion of the abdominal cavity.

RECENT ADVANCES IN THE PATHOLOGY OF CIRRHOSIS OF THE LIVER.

THE statement of Weigert that the primary lesion underlying all intestinal new growth is cell death, has been quite generally accepted, and, as applied to the liver, it is no new idea that the cirrhotic changes of the atrophic liver are purely the result of a reparative process. It is only within recent years, however, that we have learned to what a great extent and how often the parenchyma cells of the liver are capable of regenerating themselves before the interstitial new growth is permitted to become a permanent and disabling element. Kretz was the first to call attention to this remarkable regenerating power of the liver cell, and it was his opinion that only repeated and long-continued injury, as in chronic intoxication or in metabolic overwork, was able finally to produce the condition seen as cirrhosis. He based his opinion upon hyperplastic growths of liver parenchyma which he observed in early cases of cirrhosis of the liver, and his views were strengthened by many other investigations, notably those of MacCallum, Marchand, Stroebe, and Ponfick. Ponfick reported a case in which almost complete regeneration of normal tissue had taken place after the removal of a large echinoccoccus cyst of the liver, and the same author, in collaboration with v. Meister, observed true hyperplastic regeneration after the removal of from one-fourth to three-fourths of the entire liver in rabbits.

The actual process, however, in conditions analogous to those taking place in human cirrhosis have been but recently studied by Pearce. This investigator, by the injection of hemagglutinative sera into dogs, produced focal necroses in the liver, the changes in which he was enabled to study at varying intervals after injection of the serum. He found that wherever very small lesions had been produced direct repair took place without the intervention of connective tissue. Wherever, on the other hand, larger necroses had taken place, the area was first filled up by granulation tissue and then gradually replaced by young connective tissue. Along the framework of this liver cells gradually grew, until the entire area was finally again taken up by true liver parenchyma, only the denser bands of connective tissue remaining. In very large areas the process of repair was often aided by the transformation of fragments of bile ducts directly into true hepatic cells.

To the clinician a thorough understanding of Pearce's work cannot fail to be of great importance, especially in showing the great hopefulness of the prognosis, even in advanced cases, provided the cause can be removed.

SODIUM SULPHATE AS AN INTESTINAL ANTISEPTIC.

Some suggestive remarks are made by J. Maberly in the *Lancet* of November 10 regarding the true antiseptic action of sodium sulphate in intestinal toxemia. Happening to employ the remedy in cases of dysentery, with a view to free but gentle purgation, he noticed that in the dosage ordinarily used for such purgation the latter was not necessarily produced. In fact, in the most successful cases the evacuations became less frequent and assumed their normal color and consistency. These results led him to believe that the action of the remedy under the conditions named was referable to qualities other than purgative. He, therefore, began to use the drug in cases of infantile diarrhea, and found that if the dose was reduced below the aperient effect the evacuations became less frequent and often assumed a normal character without other medication. Also it was observed that vomiting quickly ceased. Milk diet was, of course, avoided as much as possible. Since obtaining such results he has relied more and more on sodium sulphate in treating all septic bowel conditions, and has become convinced that if the remedy is given in proper doses it is a true intestinal antiseptic, but to obtain this effect we must avoid doses having an aperient action. He also noted similarly good effects in typhoid fever. The effect on the bowel was as in the other conditions, and as a secondary effect the temperature curve was lowered, and the whole disease assumed a more benign aspect.

In some cases these good results did not follow, and the author suggests that perhaps in these cases there may have been some obscure alteration in the mucosa interfering with the normal splitting up of the salt. Maberly is of the opinion that the antiseptic action is due to the setting free of oxygen during the process of chemical decomposition of the drug in the bowel. Experiments by Hay have already shown that sodium sulphate produces copious intestinal secretion according to the amount of the dose and the strength of the solution. He showed further that the sulphate was split up in the intestines; the acid, being more easily absorbed than the base, disappeared partially from the small intestines to return shortly afterwards. In the meantime the base was gradually undergoing absorption and excretion by the kidneys and never pursued the same peculiar course of absorption and reexcretion as the acid. That portion of the salt which remained within the bowel unchanged caused the secretion of intestinal mucous fluid and consequent purgation, and not the portion absorbed into the blood.

NEW ASPECTS OF THE TUBERCULOSIS QUESTION.

The question of the relationship between the bacilli found in human tuberculosis and those giving rise to the disease in cattle is still under discussion by bacteriologists, and while some authorities consider the differences between the two organisms as being fundamental in nature, others are of the opinion that these characteristics are not sufficiently fixed to be regarded as infallible criterions of origin. It is especially the matter of the modifications that can be effected in virulence and cultural properties that has been a stumbling block in the way of a clear understanding of the status of the different tubercle bacilli, and even now the problem seems to be still far from solution.

Rabinowitsch and Max Koch two years ago expressed the opinion that the bacilli of avian tuberculosis were to be regarded only as varieties of the mammalian organisms, and in a recent publication (*Deutsche medizinische Wochenschrift*, November 8, 1906) the former author goes a step further, and affirms that bacilli of one form in the course of a protracted sojourn in the body of a heterogeneous animal may, through a process of gradual adaptation, approximate or acquire the characteristics of the type which is specific for that particular species of animal. This conclusion is reached as the result of the examination of many specimens of milk from tuberculous cattle, some of which were found to contain bacilli that could not be distinguished from the organisms of human tuberculosis, and of large numbers of autopsies on birds and mammals dying in the Berlin Zoological Garden. In thirty-three cases of spontaneous tuberculosis among monkeys, in most cases human bacilli were found, but there were also discovered bovine bacilli, transitional forms, and even avian bacilli. A lion and two eagles died of infection with human bacilli, and although the infections in parrots kept as pets usually is with human bacilli, Rabinowitsch found that in the Zoological Garden tuberculous parrots had only avian bacilli.

These considerations lead in the first place to the important conclusion that the external evidence is in favor of the view that the tuberculous infections of man and cattle are mutually transferable, and secondly that individual species of animals do not possess a particular susceptibility for one or the other form of tubercle bacilli, but that the determining factor lies in the particular opportunities for infection that happen to exist in each individual case.

A MITIGATION OF THE WHISTLE NUISANCE.

The Bureau of Steamboat Inspection has issued an order forbidding the use of siren whistles by any harbor steamers with the exception of government vessels and fireboats; even the latter may use their sirens only as fire alarms, and for the purpose of notifying other vessels to clear the way when they are going to fires. They must not use them on returning to their docks. Tugs and other vessels are also restricted in their use of the private signals, which have constituted the greatest nuisance on the river fronts of this city—even greater than the siren shrieks. The Supervising Inspector has ordered that, except in an emergency such as fire, private whistles to attract the attention of persons on shore or on other vessels shall not be blown. Even if compliance with this order makes it necessary to employ watchmen to call the men on the docks to

make fast lines or get ready to receive freight or passengers, still this order must be obeyed.

For the accomplishment of this reform the residents of New York, and of Philadelphia and Boston as well, to which cities the order also applies, are indebted to the indomitable persistence of Mrs. Isaac L. Rice of this town. For a year this energetic lady has carried on, almost unaided, a fight against the unnecessary noises made by the captains of tugboats and other river craft at night. Apparently worsted time and again, she persevered in the fight against almost overwhelming odds, and has finally triumphed. Mrs. Rice will have the thanks, not only of those who live near the river, but especially of the patients in the hospitals on the islands and along the water fronts who have been so cruelly tormented by these senseless noises.

CIVILIZATION AND INSANITY.

It would be but a trite statement to make that insanity has increased *pari passu* with the advance of civilization. The statement is too obvious to deny or even seriously to dispute. Opinions may differ as to the extent of the increase of insanity in civilized countries, and it may be true that exaggerated assertions in regard to the spread of lunacy are far from uncommon, but the fact undoubtedly remains that within the past fifty years insanity has increased progressively and relatively. The period mentioned has been the time when modern inventions of all descriptions have revolutionized methods of living, and, in place of a comparatively quiet and easy-going existence, life has developed into a strenuous, uneasy, nerve-racking struggle. Even the amusements of the present day present, as a rule, the same characteristics, and life in large cities has become more or less of a hurly-burly. All the conditions of our life are artificial, and this has affected the race from a physical standpoint injuriously.

The city dweller has advanced intellectually, but this advance has been at the expense of his physical state, that is to say, he has physically deteriorated, which, in turn, has affected his mental stamina, rendering him extremely prone to an upset of the mental balance. Preventive medicine, too, has undoubtedly been a factor in the increase of insanity, in that by the means now employed individuals are kept alive and breed children, who in former times would have died and not perpetuated an unhealthy stock. Thus, in a manner of speaking, we have been searching for a condition of mental instability. At one time human life was counted as naught, but with the advance of civilization life has been most carefully preserved, and consequently we have among us degenerates of all kinds, and insanity is rampant.

Some statistics regarding insanity have been issued recently in England, and these provide melancholy reading. Pauper lunatics in London alone, for whom asylums have to be provided, number now more than twenty-five thousand, while in Great Britain as a whole insanity steadily increases. In America much the same story has to be told; indeed, such is the case in all civilized countries. Things will in the course of time right themselves, but in the meantime conditions of modern life give ample room for thought, and at times one cannot avoid asking whether the luxuries and conveniences of present-day living have not been bought too dearly.

The Nature of Cancer and of Cancerous Cachexia.

As in the case of rheumatism, the true nature of cancer is still so uncertain that it offers wide opportunities to investigators for original research. The number of theories will continue to be legion until a clearer knowledge of the subject is gained. In *La Presse Médicale,* November 3, 1906, Debove reviews several of these theories which are now in vogue. He first presents certain facts: cancer consists of the development of a tumor which has a tendency, so to speak, to increase indefinitely, to recur after removal, and to form metastases; that is to say, tumors called secondary occur in the various organs. The structure of these tumors resembles that of the primary tumor. This propagation takes place by the route of lymphatics or of the blood-vessels. The theory first discussed by the writer is that of diathesis. By this is meant a congenital or acquired predisposition by which, under the influence of diverse causes, an individual may show identical reactions. As an example of this theory the following illustration is offered: After a bronchitis an individual with a tuberculous diathesis develops pulmonary phthisis, whereas an individual with the same diathesis after a contusion of the hip develops a coxalgia, and still another after gonorrhea develops a tuberculous orchitis. Although to-day the influence of the soil is admitted, another factor is necessary for the development of the disease, namely, the introduction of the specific microbe of the malady. This theory leaves us with an unsolved problem—in what does a diathesis consist? Another theory discussed is the one which looks to some parasite as the cause of the disease. Although a specific parasite has not yet been demonstrated, Debove declares that so far as he is concerned this fact is not the greatest objection to the parasitic theory, for there are a number of affections which are without doubt of parasitic origin, although the parasites have not yet been demonstrated. The greatest objection, he thinks, to this theory is the resemblance of the secondary growths to the primary focus. As a striking example, he mentions metastases in the case of melanotic carcinoma. These metastases show elements analogous to those of the tissues in which the primary tumor develops. Another theory is that of cellular anarchy. The advocates of this theory believe in the atypical growth of cells. Debove suggests that carcinoma may be considered as a sort of parasitic affection, in which the parasites are cells derived from normal cells. The general condition called cancerous cachexia is due to the difficulty experienced by certain affected organs in performing their functions.

The Use of Raw Cow's Milk for Nurslings.

In no instance is the importance of individual idiosyncrasy more marked than in the feeding of infants. Méry and Guillemot, writing in *La Tribune Médicale,* of November 3, 1906, do not pretend to be autocratic in their advocacy of raw cow's milk in the feeding of infants. They refer to a series of observations which they have made, which prove the utility of raw cow's milk as an ideal nourishment for certain nurslings. This milk has the advantages of being a living milk, containing soluble ferments

which facilitate digestion, and phosphorus in organic combination, which is destroyed by sterilization. One patient referred to was a child weighing 3,335 grams at birth. It was nursed at the breast for two months. After the cessation of secretion of mother's milk, sterilized milk was methodically given, and the infant ceased to gain in weight. It was put on raw cow's milk, and gained 530 grams in nine days. Children brought up on sterilized milk are pale and anemic; children brought up on raw cow's milk resemble those that are breast fed. The difficulty in the use of this milk is that of obtaining it in an aseptic condition. These investigators believe that in certain cases this milk offers great advantages.

Occult Gastrointestinal Hemorrhages.

As a general rule bleeding from the alimentary tract is not detected until the gastric contents or feces are sufficiently mixed with blood to give them a dark red or black color. Blood may, however, be present in microscopic amounts, when the designation of occult hemorrhage is appropriate, and it is here that an urgent necessity exists for detecting its presence as an indication of pathological processes along some portion of the canal. A number of excellent tests have been devised for demonstrating blood in such minute quantities in the stomach contents or the feces; and in all cases of suspected gastric carcinoma, for example, such an examination should be made early, even before other diagnostic aids are resorted to. Jaworski and Korolewicz (*Wiener klinische Wochenschrift*, 1906, No. 38) have made an extensive series of observations which demonstrate quite conclusively the value of such procedures. Among other things, it was also found that the hemorrhages continued in the presence of a gastric carcinoma, despite the various therapeutic measures and diet, whereas in the case of a simple round ulcer they disappeared. Although this finding does not afford any definite knowledge of the exact site of the lesion, it does furnish, in connection with other clinical symptoms, important data for diagnosis and prognosis. Boas found in cases of gastric ulcer that complete rest in bed and a milk diet were followed by a cessation of the occult hemorrhages within a period of from three to five days.

News of the Week.

Tablet in Honor of Dr. Reed.—A bronze tablet measuring three by four feet has been placed in position in the Kings County Hospital in Flatbush, in memory of the late Dr. Walter Reed, who was a former interne of the hospital. The tablet, which is the gift of the Alumni Association of the hospital, bears the following inscription: Erected by the Association of Ex-Internes of the Kings County Hospital to the memory of Walter Reed, M.D., interne in this hospital, 1871; Major and surgeon U. S. A.; chairman United States Yellow Fever Commission, 1900-1901. He robbed the pestilence of its terrors and caused the cities of the Southland to sit in peace within their gates.

Yellow Fever in Cuba.—Recent dispatches from Havana state that there are ten cases of yellow fever in the island, of which seven are in Havana, two in Cruces, and one in Guanabacoa.

Monkeys Inoculated with Yellow Fever.—In a telegraphic report from the expedition sent to Brazil by the Liverpool School of Tropical Medicine, for the purpose of investigating the yellow fever question, it is announced that the workers of the commission have been successful in proving that chimpanzees can be infected with yellow fever through the intervention of the stegomyia mosquito.

Mosquitos and Leprosy.—During the recent Congress on leprosy held at Buenos Ayres it was stated that in the province of Cordoba alone there were sixty cases of leprosy, forty-two of which were in the town of Cordoba itself. The theory that the mosquito is a transmitting agent of the disease was also promulgated.

Fire in a Bacteriological Laboratory.—At a fire of moderate extent occurring last week in the Mercy Hospital at Pittsburg, the bacteriological laboratory was in the danger zone, and, owing to the explosion of some chemicals, test tubes containing growing cultures of bacteria were broken and their contents scattered about the walls and floor. The resident physicians sprinkled disinfecting solutions about the room before allowing the firemen to enter, and the clothes of the latter were subsequently disinfected. The names and addresses of those exposed were noted, and the men are being watched for the possible development of disease.

Deaths Due to Automobiles.—The Health Department records for the second quarter of the year show that of 965 deaths occurring during April, May, and June, only eleven were caused by automobile accidents, while sixty-eight persons were killed as the result of being run over by, or thrown from, horse-drawn vehicles.

Prize Essay on Epilepsy.—A prize of $500 is offered by the Association for the Study of Epilepsy for the best essay on the etiology of epilepsy; the conditions of award are as follows: All essays submitted must be in English, and must not contain more than 15,000 words. Essays must be in the possession of Dr. W. P. Spratling, at Sonyea, N. Y., not later than September 1, 1907. The name of the person submitting the essay must not appear on the same, but be put in a sealed envelope on which is written a motto, which motto should also appear at the top of the first page of the essay. The essays will be judged by a committee of three, and announcement of the award will be made at the November, 1907, meeting of the Association. The Association will not feel bound to award the prize should no essay submitted be deemed of sufficient value to merit it.

Laryngologists Wanted.—The Board of Health announces that there are a number of vacancies in the staff of attending physicians and laryngologists of the Manhattan Tuberculosis Clinic, conducted by the Department. Classes are held three times a week—in the morning, afternoon, and evening. The Department of Health states that it hopes in the near future to remunerate the clinic physicians for their services. Those desiring to apply for the above mentioned positions should call at the office of the Division of Communicable Diseases, Department of Health, Fifty-fifth street and Sixth avenue, New York, N. Y.

Report of the Cook County Coroner.—In his November report, the Coroner of Cook County, Ill., points out an increase in the number of deaths for October over the preceding month, the respective numbers being 351 and 308. In October there were 46 suicides, as compared with 36 in September. Of this number, 18 died from gunshot wounds, 9 from poison, and 10 from asphyxiation.

The Philadelphia Clinic for Home Treatment

of Chest and Throat Diseases, 519 South Fifteenth street, Philadelphia, has recently opened evening clinics, in addition to the day clinics which have been running since last March, for free treatment to the consumptive poor. It is estimated that about one-third of the 9,000 consumptives living in Philadelphia annually earn over $1,000,000, but without medical care will in a few years become unfit to work, and in all probability many of them will have to be maintained in hospitals at an added expense of another $1,000,000, making a total loss in wages and in cost of maintenance of over $2,000,000 a year. The object is to lighten the struggle of these people during this trying period of their life, to help save their wages, and to forestall the danger of becoming public charges. Dr. Frank Read is President of the Board of Managers, and Dr. Thomas J. Mays is Medical Director of this institution.

Columbia University.— At a recent meeting of the Board of Trustees of Columbia University the degree of Doctor of Science was conferred on Sir William Henry Perkin, regarded as the founder of the modern coal tar chemistry. A gift was announced of $3,440 to provide additional clinical facilities for students of medicine, and one of $500 to purchase instruments for the Sloane Maternity Hospital.

Harvey Society Lecture.—The fourth lecture in the Harvey Society Course will be delivered by Prof. J. G. Adami of McGill University, Montreal, on December 1, at 8:30 P. M., at the New York Academy of Medicine. Subject: "The Myelins and Potential Fluid Crystals of the Body." All interested are cordially invited to attend.

Dr. H. S. Frenkel of Heiden, Switzerland, read a paper on the educational treatment of locomotor ataxia at the monthly meeting of the Medical Society of the County of New York on Monday evening of this week. During December he will give a course of lectures and clinical demonstrations at the New York Polyclinic in Dr. Pritchard's hours on Mondays and Fridays, from 1.30 to 2.30 P. M.

Dr. W. P. Spratling of Sonyea has been elected a member of the Executive Committee of the New York State Conference of Charities and Correction, and Chairman of the Committee on Medical Defectives of the same association.

Dr. L. W. Bremerman has been appointed Professor of Genitourinary Diseases in the New York School of Clinical Medicine, to fill the vacancy caused by the death of Professor William K. Otis, M.D.

Dr. Henry Sykes has been appointed Chief Resident Physician to the Philadelphia Hospital, having passed successfully a Civil Service examination.

Training School for Nurses in Paris.—As the result, it is stated, of the recent visits of French physicians to England, the Parisian authorities are to establish a training school for nurses founded on English models. The new building will be erected near the Salpetrière, and almost next door to this institution will be built the new hospital of La Pitié. The course is to last three years, of which the first two will be theoretical and the last practical.

Jewish Hospital of Brooklyn.—At a meeting of the Jewish Hospital Society of Brooklyn it was announced that the hospital building, at Classon and St. Mark's avenues, would be dedicated on December 9 and opened on the following day for the reception of patients. The land, building, and equipment represent an outlay of about $350,000. For the present the accommodations provided will be limited to seventy-five or one hundred patients. Dr. Jacob Fuchs will be the chief physician and Dr. H. Beeckman Delatour chief surgeon.

International Laryngo-Rhinological Congress.—This will be held in Vienna April 21 to 25, 1908, and is to be conducted as a memorial to Türck and Czermak, in order to commemorate the fiftieth anniversary of their labors in developing modern laryngology. Papers may be read in German, English, or French, and together with an abstract of their contents should be in the hands of the secretary not later than December 31, 1907. The president is Prof. O. Chiari of Vienna, the honorary president of the Congress will be Prof. W. Schrötter of Vienna, and the secretary is Prof. M. Grossmann, Vienna, IX., Garnisongasse 10.

Middle Tennessee Medical Association.—At the meeting held in Shelbyville officers for this society were elected as follows for the ensuing year: *President,* Dr. W. G. Friersen of Shelbyville; *Vice-President,* Dr. Douglas of Nashville; *Secretary,* Dr. Litterer of Nashville.

Fond du Lac County (Wis.) Medical Society.—At the annual meeting of this society, held in Fond du Lac, the following officers were elected: *President,* Dr. J. W. Burns, Oakfield; *Vice-President,* Dr. G. F. Scheib; *Secretary and Treasurer,* Dr. Flora A. Read.

Tri-State Medical Association of Louisiana, Texas, and Arkansas.—At the recent meeting of this organization held in Marshall, Texas, the following officers were elected: *President,* Dr. Holman Taylor of Marshall; *Vice-President* for Arkansas, Dr. A. U. Williams of Hot Springs; *Vice-President* for Louisiana, Dr. J. L. Wilson of Alexandria; *Vice-President* for Texas, Dr. Becton of Greenville; *Secretary,* Dr. R. H. T. Mann of Texarkana, Ark.; *Treasurer,* Dr. I. M. Calloway of Shreveport, La.

The Late Dr. William K. Otis.—At a meeting of the Medical Association of the Greater City of New York, held November 19, 1906, the following resolutions were presented and adopted:

Whereas, It has pleased Almighty God to remove from our midst our colleague, Dr. William K. Otis, therefore it is

Resolved, That we express our sincere sorrow at the loss we have sustained; that we are duly conscious of his high personal character and his genial and attractive personality, and that we are proud of his advanced position in medicine and of his well-earned fame as a specialist in genitourinary surgery.

Resolved, That we extend the heartfelt sympathy of the Society to the family of the deceased, and that these resolutions, expressive of grief and condolence, shall be transmitted to the local medical journals, to wit, the MEDICAL RECORD and the *New York Medical Journal,* with the request that they be published in their columns.

Resolved, That a copy of these resolutions be sent to the family of the deceased member.

(Signed) ROBERT W. TAYLOR, RAMON GUITERAS, ROBERT HOLMES GREENE, *Committee.*

At a united meeting of the Faculty of the New York School of Clinical Medicine and the Trustees of the West Side German Dispensary, held October 31, 1906, the following resolutions were adopted:

That, *Whereas,* on September 22, 1906, through the sudden and untimely decease of our beloved confrère, William K. Otis, M.D., professor of Gen-

itourinary surgery, we have sustained a grevious loss; and

Whereas, The Clinical School has lost its most trustworthy secretary and excellent teacher; the Dispensary a faithful adherent; the profession a scientific inventor; the public a skilful practitioner; his associates a most estimable colleague; and his intimates a loyal, open-hearted, self-forgetful friend; therefore, be it

Resolved, That we, deploring our loss, share with the bereaved family of William K. Otis their sorrow and grief, and hereby tender our heartfelt sympathy; and be it

Resolved, That copies of these resolutions be spread in full on the minutes, published in the medical journals, and a copy thereof sent to the afflicted family of the deceased.

(Signed) A. Ernest Gallant, M.D.; John L. Adams, M.D.; William Friedman, *Committee for the Faculty and Trustees.*

Obituary Notes.—Dr. John A. Laros died at Coopersburg, Pa., on November 15, at the age of sixty-eight years. He was graduated from the medical department of the University of Pennsylvania in the class of 1862.

Dr. Charles E. Wetton died at Camden, N. J., on November 18, at the age of thirty-two years. He was a graduate of Jefferson Medical College.

Dr. Wm. Muir Angney died at Philadelphia on November 19, as a result of carcinoma of the stomach, at the age of forty-six years. He was graduated from Jefferson Medical College in the class of 1882. He served as resident physician in the Philadelphia Hospital and subsequently became District Physician to the Board of Guardians of the Poor, later Vaccine Physician, and then Assistant Medical Inspector of the Bureau of Health. Since 1902 he has been Chief Surgeon to the Bureau of Police. He was physician to the Protestant Episcopal City Mission and Visiting Physician to the Hospital for Diseases of the Lungs at Chestnut Hill and the Hospital for Male Consumptives of the House of Mercy.

Dr. Leonard Francis Nicoll of this city died of typhoid fever on November 25, at the age of thirty-one years. He was graduated from Harvard University in 1899 and four years later received his medical degree from Columbia.

Dr. Isaac E. Atkinson of Baltimore died of pneumonia on November 24, at the age of sixty years. He had held many official professional positions.

Dr. Clark R. Wilcoxson of Ypsilanti, Mich., died on November 13, at the age of thirty-six years. He was graduated from the University of Michigan Medical School in 1894 and had practised in Ypsilanti ever since. For a number of years he was health officer of Ypsilanti.

Dr. Lorenzo M. Greene of Bethel, Vt., died on November 12, at the age of fifty-four years. He was born in Rochester and studied medicine at the Dartmouth Medical College and the University of Vermont. He had practised in Bethel since 1877.

Dr. James F. Winsell of Redding, Cal., died on November 10, at the age of eighty-one years. He was a native of Indiana, but went to California immediately upon being graduated from the Ohio Medical College of Cincinnati in 1849.

Dr. Ruth Marvin of Sioux City, Ia., died on November 11, at the age of thirty-seven years. She was the wife of Dr. H. M. Marvin and was graduated from Yankton College in 1880. She received her medical degree from the Hahnemann Medical College in Chicago twelve years later. Since 1896 she had practised in Sioux City.

Dr. William M. Barrett of Westboro, Mass., died on November 10, at the age of eighty-four years. He was a graduate of Bowdoin College and received his medical degree from the medical school of that institution in 1846. He served as assistant surgeon through the Civil War.

Dr. George B. Moore of St. Paul, Minn., died on November 14, of pneumonia, at the age of thirty-five years. He was graduated from the Medical School of the Minnesota State University and three years ago was made police surgeon of St. Paul.

Dr. John J. Hill of Atlanta, Ga., died on November 12, at the age of fifty-four years. He was graduated from the Bellevue Hospital Medical College about twenty years ago and had practised in Atlanta ever since.

Dr. Wm. M. Thompson of Opelousas, La., died on November 11, at the age of fifty-seven years. He was graduated from the medical department of Tulane University, New Orleans, in 1872, and immediately began practice in Opelousas.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BIRTHDAY HONORS—THE LATE MR. GEORGE HERRING—UNIVERSITY COLLEGE NEWS—THE TREATMENT OF MENORRHAGIA—VIOLA ODORATA—FEEDING SCHOOL CHILDREN—AND SOCIALISM—LONDON MILK AND ITS SUPPLY.

London, November 9, 1906.

To-day being the King's birthday, the customary list of honors conferred on the occasion was issued last night. Most of the persons selected by the government for this Majesty's approval are political partisans, but half a dozen medical and scientific men are recognized by a knighthood—not a single baronetcy is conferred on such, though one would have thought the presidency of the Royal College of Surgeons might have been so distinguished. But Mr. Tweedy takes his place with the other knights, viz., Professor Byers of Belfast, Prof. Rubert W. Boyce of Liverpool University and the Tropical School, and Dr. Ch. F. Hutchinson, who was a member of the last parliament but lost his seat at the general election. The C. M. G. is given to Mr. S. W. Thompstone, F.R.C.S., Principal Medical Officer of Northern Nigeria, and to Mr. W. T. Grenfell, M.R.C.S., Medical Superintendent of the Royal National Mission, to Deep Sea Fishermen.

The death of Mr. George Herring, the munificent philanthropist to whom our hospitals are specially indebted, came as a shock to those interested in these charities. Ever since 1899 the Sunday fund has received an annual contribution from him of over £10,000, and his other gifts to such institutions and various charities were on a most generous scale. His body was cremated on Wednesday, in accordance with his will, the provisions of which were made public on Thursday. Apart from family and private legacies he leaves the North West London Hospital, of which he was treasurer, £5,000; Maidenhead Cottage Hospital, £500; the Charitable Relief Society, £1,000. His town residence and contents, subject to some personal souvenirs, are to be sold for the benefit of King Edward VII's hospital fund. The residue of his property, after numerous provisions of less public interest, goes to the Hospital Sunday Fund, and is expected to amount to half a million sterling. Provision is made to carry out his gift of £100,000 to the Salvation Army's social scheme.

On Tuesday the Duke of Connaught, accompanied by the duchess, went to the University College Hospital and declared the new building open. Their Royal Highnesses were received by the Duke of Bedford, president of the hospital, Lord Reay, president of the college, and a very distinguished company, including the staff of the hospital and professors of the college. You will remember that this hospital has been rebuilt at a cost of £200,000, provided by the late Sir J. Blundell Maple. The main building is cruciform in design, the material red brick with terra-cotta dressings. The wards to accommodate 300 patients are in the arms of the cross. The board room and operating theaters are in the central block. The out-patient department, baths, and rooms for Finsen light and Roentgen ray treatment are located in the basement. An address was

presented from the committee and staff in which regret was expressed that Sir J. B. Maple had not lived to see the completion of the building. The duke made an admirable reply, closing with an appeal to professors and collegiates who "follow men who have thrown a great luster on the medical profession, men who have been a blessing to the world," and adding, "I am certain that the rising members of the medical profession will ever do all they can to keep up the noble attributes of the English doctor."

Menorrhagia so severe as to endanger life and quite uncontrollable by ordinary methods has been met sometimes by hysterectomy. To many the remedy seems desperate, but if no special cause can be detected, no polyp, no fibroid, no cancer, and yet the life of the patient is threatened, the gynecologists are for the most part agreed that operation must be resorted to. The question was considered at the Gynecological Society, when the president, Mr. Bowerman Jessett, showed a specimen from a case which well illustrated the difficulties that may be encountered. The patient had been reduced to the state of a confirmed invalid. Digital examination was negative, even after dilating the canal under an anesthetic. Mr. Jessett thought there was probably a submucous fibroid of the fundus beyond reach, as the cavity was of great length. He removed the uterus and the patient did well. On cutting open the uterus a fibroid (shown) the size of a walnut was found at the fundus close under the membrane. The president compared the case with another which he had thought must be cancerous and had operated on with excellent result, and said he had seen many women who had suffered severely and been curetted several times without relief. If nothing can be discovered by explorations after dilatation, he thought it time to remove the uterus.

Dr. Howell Evans agreed with the president. The scientific treatment was to observe for a time under palliatives and note the anemia by blood counts between the periods. If that increased ground was being lost and it was proper to weigh whether the loss of an abnormally active organ by its removal would preserve the patient's life.

Professor Kinkhead thought that was going rather too far. He had had many cases with profound anemia, no cause being discoverable by any diagnostic proceeding, curetted, watched, and later showing a fibroid or polyp; also many cases in which this did not occur, but which depended on want of normal contractile power, curetting had been useless, but the steady use of phenol and iodine to the inside of the organ brought about recovery. In one case in which he had had to plug complete cure ensued after the application of iodized phenol to the uterine cavity twice a week for two months. His experience was opposed to hysterectomy for hemorrhage in any case.

Dr. C. H. Bennett had seen severe cases cured by gallic acid in 10 grain doses, and would not operate until after trying that treatment unless a fibroid or polyp could be detected.

Dr. Purcell said other means were, of course, usually tried before operation, as calcium sulphide, hydrastis, or any astringent.

Mr. Ryall said it was easy to be wise after the event, but, looking at the specimen, it seemed to be a matter for dilating the cervix rather than hysterectomy—it looked as if it could be enucleated. The first and most important treatment was rest in bed. All sorts of drugs might be given, but it was the rest that did the good. If no reasonable treatment availed and no tumor could be detected, the organ was useless and a source of danger, too.

The president said in reply, that the fibroid could not have been snared, as it was submucous and somewhat interstitial. The uterus was very large—3½ inches—and the top could not be reached. Hence it was not certain there was a fibroid. The finger could pass far enough to be pretty sure there was no polyp. Of course, had there been, it could have been removed and the uterus saved. He thought the result justified the operation. The patient was a widow with seven children dependent on her. He might have kept her in bed and given a pint or more of gallic acid mixture and so abated the hemorrhage, but all the gallic acid in the world would not have cured her while she had the fibroid. He agreed with Prof. Kinkhead as to iodized phenol, but nitric acid was still better. Of course, it was necessary to pack the vagina with sodium carbonate solution, to prevent burning. He held, however, that in such a case as he had brought before them, in which no cause could be detected, it was right to remove the uterus.

From time to time the newspapers repeat misleading statements about the cure of cancer and other diseases. These irresponsible editors do not seem to appreciate the cruelty of exciting false hopes in sufferers or the degradation of promoting quackery. They have again been circulating foolish stories about the value of violet leaves in cancer. Though the plant is admitted to have some influence on the animal functions, the assertions of such value have long been refuted.

In December, 1905, Mr. Whipple Gadd, F.C.S., communicated to the Therapeutic Society a searching research into the chemistry of the plant. I reported his results at the time as practically negative. On the 30th ult. he communicated further investigations with a similar result. He has searched in vain for an alkaloid or for a glucoside. He is unable, therefore, to confirm Mandelin's reported discovery of viola-guercitrin in the leaves. Attempts to isolate a ferment were equally unsuccessful. Varying amounts of glucose in different samples, gathered at different times of the year, were the chief result, and anything like an active principle remains unknown.

A paper on the therapeutics of viola odorata was read by Dr. W. A. Potts, who showed tracings of the pulse, blood pressure, and frog's heart. He found a definite although transient depressor effect on all parts of the circulation and suggested that it would be unwise to give the drug in cases of feeble heart action. He noticed after taking it that the urine resisted decomposition for several days, even in hot weather, which seemed to indicate an antiseptic action of some product in the secretion, and might account for decreased foulness of discharges which had been noticed during its use. He also found local applications relieved pain.

Dr. Parker Douglas agreed that preparations of the leaves mitigated pain and the foulness of discharges.

Sir L. Brunton confirmed these two points from his trials and mentioned the similar effects of saponins and hoped Mr. Gadd would search for saponins in the plant; these produce transient irritation of the skin, followed by an anesthetic effect.

On Wednesday Sir Wm. Chance, lecturing on socialism to a select audience, while admitting that State interference in social affairs might sometimes be temporarily beneficial, said it was harmful by weakening character, lessening parental responsibility, and inducing people to rely on the State instead of themselves. Free education was a doubtful measure and had led to a demand for feeding school children. Tampering with the poor law so common of late was clearly mischievous and tended to kill individual efforts to meet the evils of our civilization.

In connection with this it may be added that at a meeting held last week to promote some practical way of feeding school children an unexpected opposition to the proposal was expressed. The chairman, Mr. Bridgeman, M.P., said the children suffered more from neglect and dirt than underfeeding. Sir C. Elliott moved a resolution that it is contrary to the interests of the State to feed the school children or for the rates to be charged with the duties of parents. One speaker thought otherwise, and said charity would break down, but the meeting carried the resolution against him and another advocating medical supervision.

The report of a committee on milk supply appointed by the Royal Institute of Public Health has just appeared and emphasizes the necessity of further steps for the prevention of milk-borne diseases. The chief ones are stated to be typhoid and scarlet fevers, diphtheria, tuberculosis, and epidemic diarrhea. The supply of milk in London and large towns is said to be insufficient in quantity and sadly deficient in quality, enormous numbers of bacteria, pus cells, and other impurities being contained in a large proportion of samples. Early and rapid souring indicates uncleanness, to prevent which preservatives are commonly added by 50 per cent. of the dairymen. Legal control of the business is demanded. The powers possessed are not nearly so strict as in many colonies, and the committee mentions a number of reforms which could easily be introduced by modifications of the Milk Shops Order of 1855, which in rural parts has become a dead letter. The feeding of the cows, their veterinary inspection, and isolation when ill are considered, and these points followed by suggestions on the transit of milk.

OUR PARIS LETTER.

(From Our Special Correspondent.)

SYPHILIS IN THE VIRTUOUS—THE ETIOLOGY AND TREATMENT OF MALARIA—MILIARY FEVER—AUTOMOBILING AND HEALTH—RAW MILK IN INFANT FEEDING—GAS INJECTIONS IN PLEURISY.

PARIS, October 28, 1006.

ON October 2 the Académie de Médecine resumed its sessions. Professor Fournier presented a very interesting paper on syphilis in pure women. He said that, according to his own personal statistics, out of every one hundred syphilitic women twenty were married and virtuous. His

endeavor had been to determine under what conditions these women were infected, and he believed that the disease was transmitted in two ways, either the husband was syphilitic before marriage, or he became so afterward. The first state of affairs was much commoner than the second, since for 218 cases of conjugal syphilis due to premarital infection of the husband there were only 94 cases of the second type. Under what conditions do these husbands that were previously syphilitic communicate the disease to their wives? In this respect extreme variability is observed. Sometimes the infection takes place very promptly, on the 28th day in one case, and usually it occurs during the first month, or at least during the first year of married life. Out of 151 cases in 130 instances contagion took place during the first year, and 117 times during the first six months. The disease in these husbands is usually of recent date, being of less than three years duration in 98 cases. These examples show that many syphilitics marry too soon. To some degree the fault lies with the physician who still too often contents himself with a treatment of insufficient duration, but it is mainly the patient who is to blame for marrying, either through ignorance or through lack of consideration, knowing himself to be syphilitic. Fournier urged the necessity of greater efforts in prophylaxis founded on the dissemination of instruction relating to syphilis. Although syphilis in married women is often prompt to appear, sometimes it is very late in developing, as in some cases seen by the author in which the husband had had his chancre from seven to nine years previously. Usually the reason for the infection is to be sought in the presence in the husband of secondary lesions, oftentimes delayed, but which must not be regarded as harmless. The mucous patch especially loses none of its contagiousness simply because it is late in appearing. Numerous recorded observations bear witness to this fact, which should be impressed on both physicians and the general public, as it is too often believed that syphilis of long standing is devoid of danger. Fournier drew some practical deductions from his study. In the first place, he pointed out the necessity for a prolonged course of treatment for every syphilitic, especially if marriage was being considered. It was also necessary, he said, for every syphilitic about to marry to give up the use of tobacco, since its use was likely to evoke the development of secondary buccal lesions even much later than the secondary period. These desiderata were difficult to secure, however, and, on the other hand, it was well known that every woman infected by her husband was condemned, except in rare instances, to receive only insufficient treatment, and therefore to be exposed to all the dangers of the disease when imperfectly controlled.

The etiology and prophylaxis of malaria were discussed by M. Kelsch. He said that he regretted to see the modern nonobservance of those wise and certainly effective prophylactic measures made use of by our predecessors in combatting this disease, which they attributed to emanations from the soil. Nowadays these procedures have been abandoned in order to give undivided prominence to mechanical protection against the anopheles. The speaker asked himself the question whether malaria were transmitted only through mosquitos, and he cited instances of extremely severe epidemics which had claimed as their victims soldiers or colonists who came into close contact with the soil, and which spoke in favor of an injurious rôle played by the earth or dust. He further pointed out that the numerous patients coming from the colonies and distributed during their convalescence in the most widely separated regions of France never gave rise to epidemics in spite of the presence of many mosquitos in these places. Finally he referred to the variations in virulence shown by the disease in malarial countries, and said that he considered that many things suggested the existence of secondary causes in the development and spread of the disease. Although the combat against the mosquitos was perfectly justifiable, the old measures, particularly those relating to the soil, should not be neglected.

A report by M. Nicloux on the absorption of chloroform by the organs and tissues was read by M. Grehant. By means of a special method Nicloux was enabled to study the details of chloroform anesthesia. In the dog the anesthetic dose was in the neighborhood of 50 mg. for 150 c.c. of blood; the fatal dose in the neighborhood of 70 mg., showing that only a very slight margin of safety exists. Chloroform is quickly eliminated from the blood, but becomes fixed in the tissues, the brain and medulla especially absorbing large amounts. Finally, chloroform passes from the mother to the fetus and into the milk of nursing women.

Chantemesse, Marchoux, and Haury have presented the results of an interesting investigation on miliary fever and rats. They reported observations made in the course of an epidemic of this disease occurring last May and June in Charent and Deux-Sévres, which led them to suggest an etiological possibility in which the rat plays a part. This epidemic involved 6,000 persons, and in forty-five days it had covered its area of dissemination. It was localized entirely in the rural districts, cities situated in the same region escaping. Patients taken into cities for treatment failed to cause any spread of the malady. On the other hand, it was found that miliary fever could be transmitted without the intervention of the patients. The infective agent seemed to come from the fields, and the first houses invaded in a village were always those on the outskirts. It also appeared to be telluric in its origin, or at least it was most apt to attack those who slept on or close to the ground. These considerations led the authors to believe that, as in bubonic plague, the rat might be the carrier of the virus, and many facts were elicited which appeared to confirm this view. The fleas of the rodents are supposed to be the active agents in performing the inoculation. Experimental proof is still lacking, however.

At the Société de Therapeutique M. Legendre discussed the influence of the automobile on health. He said that the rapid displacement of air at the surface of the body gave rise to vasoconstriction which was followed by vasodilatation on stopping, and these modifications of circulation could influence certain dermatoses. He had seen one patient suffering from pruritis which had proved obstinate to all other forms of treatment cured under the use of the automobile. Some emphysematous patients and asthmatics of the nervous type profited by automobiling, but it should be forbidden for tuberculous patients with fever, though it might be allowed if the lesions were discrete and without any tendency to congestion. Chlorotic patients might benefit by short trips, and motoring might be permitted for persons with well-compensated cardiac lesions. It should be forbidden to those with pulmonary or hepatic congestion. Patients with varicose veins could not, without disadvantage, remain for a long time motionless in carriages. Motoring, he said, was beneficial for many gastric conditions, but was inadvisable for patients with ulcer of the stomach. Nephritics and women with uterine disorders might make use of the automobile if there was no tendency to congestion, and gouty and diabetic individuals also profited by it. Obese automobilists were apt to get out of the way of walking and did not take sufficient exercise. Nervous patients of the depressed type were benefited by motoring, but those of excitable nature were made worse, especially if they attempted to drive themselves. The same thing was true for epileptics, and all persons desirous of driving motor cars should be subjected to a medical examination.

The use of raw milk in infant feeding was discussed in the Societé d'Obstetrique, de Gynecologie, et de Pediatrie by MM. Mary and Guillemot. They said that raw milk was living milk, containing living soluble ferments capable of acting on the fat, the lactose, and perhaps even on the proteids. The phosphorus contained in it was also more easily assimilable, and the citric acid played a rôle which was not negligible. There were serious objections to its use, however, owing to the difficulty of obtaining it sufficiently free from germs, and the food of the cows also required consideration. They believed that raw milk should not be employed as a matter of routine, but that in some cases when it could be adequately safeguarded by the producer it might give marvelous results.

At the meeting of the Société Médicale des Hôpitaux M. Vaquez spoke on the treatment of pleurisy by the injection of gases. This, he said, was done with a double end in view, either of inhibiting a tuberculous process or of treating the effusion itself. The first of these indications had recently received consideration in Germany, where in the absence of pleurisy an artificial pneumothorax had been induced in the treatment of tuberculosis. The author considered that in cases of acute pleurisy the duration of the disease itself was abridged, and that in cases of recurrence the injection of gas was the treatment of choice. The procedure had the mechanical effect of allowing the expansion of the lung to take place only very slowly; it was therefore necessary to use some gas which was not absorbed too quickly. Nitrogen was to be preferred, as it was not injurious and remained for a long time in the pleural cavity. The author was able to demonstrate its presence eight months after the injection. The amount to be used was variable, and ordinarily equaled about half the quantity of fluid removed.

The Long Island Society of Anesthetists will hold a regular meeting on Tuesday evening, December 4, at 8.30 P. M. at the Cumberland Street Hospital. Papers will be read by Drs. Clark Burnham of the Cumberland Street Hospital, Longstreet of the Norwegian Hospital, and Pedersen of Roosevelt Hospital.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

POSTGRADUATE STUDY—NOORDEN'S INAUGURAL ADDRESS—SEMMELWEIS MEMORIAL—A RADIUM SPA—EXTRAUTERINE PREGNANCY—LARYNGEAL OPERATIONS.

VIENNA, October 23, 1906.

THE Aerztekammer has this month put in operation a project intended to facilitate the postgraduate study of physicians who are engaged in active practice, and therefore have but little free time at their disposal. Postgraduate courses are to be given throughout the entire year at hours at which even a busy practitioner will have time to broaden his professional attainments. It is the intention in this way to offer practitioners the opportunity of keeping themselves in touch with advances in medical research and to acquaint themselves with the modern developments of science. All of the professors and assistants of the University of Vienna will take part in the courses.

On October 17 Prof. Carl von Noorden delivered his inaugural address on his assumption of what was formerly Nothnagel's clinic. Almost all the members of the faculty were present to greet Noorden, whose reputation, especially in the domain of diseases of metabolism, is so great that our university has gained in importance and standing through his coming. In his address Noorden delivered a glowing eulogy of Nothnagel and praised him as clinician, teacher, and man. He then discussed the position of the medical clinic in the instruction of the medical students, and said that the clinical teaching might be divided into the introductory part, clinical instruction itself, and the therapeutic part. He reviewed with telling force the separate components of the material available and compared our methods with those of the German and American universities. Noorden intends to educate his forces in the clinic along pedagogic lines so that his pupils may be better educated in all departments of diagnosis and treatment. He also discussed postgraduate work and said that he considered it an important matter that should be fostered by all the professors. In speaking of the problems of therapeutics in internal medicine, he warmly commended the innate optimism of the general practitioner. With the general applause of those present he closed his discourse and assumed the direction of this well-known clinic, whose reputation has in the past attracted so many foreigners to the university.

On September 29 the celebration in honor of Semmelweis was held in Budapest. Professor von Gyory delivered an eloquent memorial address in which he described the personality of the eminent scientist and great-hearted man who, through his fight against puerperal fever, had rendered such invaluable service to mankind. On the following day the ceremonies were continued in the university, and were closed by the unveiling of the Semmelweis monument on the Elizabeth Promenade. Some of the most prominent gynecologists of Europe were present, and in their addresses paid tribute to the merits of this immortal man. The monument itself represents Semmelweis in his prime; at the base of the pedestal is seated a female figure looking toward the scientist with grateful eyes while holding her infant to her breast. A memorial tablet placed on the house in Ofen in which Semmelweis was born was also unveiled under appropriate ceremonies.

Austria is to have a radium spa, although the time of its completion is still somewhat indefinite. More than two years ago the Academy of Sciences of Vienna received from the Government 10,000 kg. of uranium ore from the mines of Joachimstal for the study of radium. This enormous quantity of the raw material was brought to Vienna by the carload and the extraction of its radium content was entrusted to Dr. Heitinger. This task is now nearly completed and an amount of pure radium has been secured which, according to the present market price, has a value of 1,000,000 crowns, and which will first be handed over to scientific institutions for purposes of research; for example, the question of the radiation of heat by radium is to be investigated by a new method. A special laboratory for the production of radium salts is to be established in Joachimstal, and it has been proposed to use the springs in the shafts as therapeutic baths, and also to make use of this strongly radioactive water internally. With this end in view these spring waters are being carefully analyzed in Vienna in order to determine their mineral components. As soon as these investigations are completed and the necessary work has been done in the mines a sanatorium is to be erected in Joachimstal.

Dr. Stephen Toth has operated on a case of extrauterine pregnancy at term with a living child. The patient was a woman of thirty-five years who had had two normal labors, the last of which was ten years ago. On examination, the diagnosis of extrauterine pregnancy was made, as the fetus could plainly be distinguished outside of the uterus. At the laparotomy it was found that the left tube was normal for five or six cm. from the uterus, and it then suddenly became dilated and expanded into the fetal sac, which was adherent to the left broad ligament and the uterus. On rupturing the membranes a living child was found with the breech in the pelvis, the head upward and to the right, and with one leg extended and the other foot beside the breech. The child was easily resuscitated and the mother made an uncomplicated recovery. The child was thirty-five cm. in length, had a weight of 3,000 g., and its skull measured fifty cm. in circumference. The foot, which was next to the breech, is a pes varus, and the knee is contracted at an angle of 150°, but otherwise the child is developing normally.

A plastic operation on the anterior wall of the larynx has been performed by Dr. Nauratil The patient was a man of thirty years, who, in an attempt at suicide, cut through his larynx at the level of the vocal cords. The hemorrhage was profuse and the man went into collapse. After resuscitation tracheotomy was done and the transverse wound was sutured. The patient was very restless and tore the wound open again, and in consequence of the suppuration that ensued there was great loss of tissue, which resulted in constant escape of food and saliva from the wound. After the tube had been removed and the tracheal wound had healed severe dyspnea ensued, so that another tube was placed in the laryngeal opening. The treatment of the injury was further complicated by a widespread eczema of the entire neck. A low tracheotomy was done, and after the eczema had been cured Nauratil closed the defect in the larynx with two large flaps formed from the side of the neck, and secured complete closure of the wound in this way. After the patient had been breathing for six months with the tube closed this was removed. The patient is now able to swallow perfectly, and is able to make himself understood, although he has no vocal cords. In phonating he makes use in their stead of the transplanted flaps. Another interesting laryngeal case has been presented by Albrecht. This man's entire larynx had been excised on account of carcinoma, and the patient had succeeded in devising for himself a simple but effective apparatus for speaking. It consisted of a rubber tube, which he passed into the pharynx in order to secure a necessary current of air, while the voice itself was produced by an appliance adapted to the tracheotomy tube. By the aid of this mechanism the patient can make himself understood even at a distance of twenty paces.

OUR DUBLIN LETTER.

(From Our Special Correspondent.)

DUBLIN, November 3, 1906.

ANOTHER October has come and gone; a new *Annus Medicus* has been ushered in to offer its opportunities and drawbacks to the pilgrims on the pathway of medical education; and the doorways of the numerous medical schools and the innumerable hospitals of the Irish metropolis now stand widely open and seem mutely to invite the entrance of the adolescent dreamer of dreams—of future medical and surgical distinction. The time-honored custom of welcoming and advising—as well as attracting—the junior Æsculapian band at each of the teaching institutions through the medium of an "Introductory Lecture" at the opening of each winter session has, of recent years, gradually been falling into abeyance. And in the present year the annual rite has been performed in two only of the Dublin hospitals, the Meath and St. Vincent's. It is specially interesting, in the present stage of Ireland's emergence from the political gloom of many centuries, and its rapid bloodless progress through an epoch-making revolution, to observe that the conservative course has, on this occasion, been adopted by the leading representative hospitals of the conservative and nationalist parties and interests, respectively. The former institution has for a century and a half or so been the foremost institution of its kind—as representative of Protestant interest and science, under the influence of protective English ascendancy—in Dublin, and we may gratuitiously add, in all Ireland. St. Vincent's Hospital (necessarily), of junior growth, may be regarded as a blossom of the successful movement of "Catholic Emancipation" in the same country; when the lurid cloud of religious and social proscription was, after an existence of centuries, torn—but not yet rolled back—over the heads of the majority of the population of Ireland. Accordingly the incident of a single pair of "Introductories"—so chosen—thus arranged in the Irish metropolis is looked upon as surely significant; even prophetic. That at the former hospital was delivered by Sir Lambert Hepenstal Ormsby; at the latter by Mr. John Stephen McArdle. The Meath

Hospital was founded by the representative scion of a Protestant aristocratic house, and has, in inevitable accordance with this origin, always formed a symbol of the English ascendancy in and settlement of the Emerald Isle. St. Vincent's Hospital owes its existence to the exertions of an Irish Catholic lady who adopted a saintly life of celibacy and retirement in preference to the pursuit of the pomps and vanities of a wicked—and disappointing—world, and devoted her person, her time, and all her available energies—physical and intellectual—as well as all her material earthly possessions to the glory of God and the improvement of the physical (as well as spiritual) condition of her suffering fellow-creatures in the progress of their painful life pilgrimage.

The introductory lecture at the Meath Hospital opened with a brief historic sketch of the institution and its recent onward progress in the van of the intellectual march of surgery. Forty years ago the lecturer became an apprenticed pupil. Antisepsis and asepsis were then undreamed of in the practice of their hospital theaters and wards—and now! With characteristic modesty Sir Lambert Ormsby passed over the unique part which he had himself played in the introduction of antiseptic surgery. Nor did Sir Lambert Ormsby allude to his own exertions in the introduction of orthopedic surgery into Ireland, where he made himself its first apostle; nor to his classical volume on this specialty: "The Deformities of the Human Body." The lecturer then proceeded to call attention to the crying grievances which still exist in the military and naval medical services.

The Meath Hospital has always been peculiarly fortunate in its literary scientists. Robert Graves and William Stokes the pioneers of modern clinical teaching, raised its fame by their clinical lectures and published writings to a higher level than that of any other institution of its kind in existence. The mantle of Stokes has, happily, fallen on the shoulders of his accomplished successor, Sir John Moore, whose work on the "Continued and Eruptive Fevers" has for years been the foremost English classic in this very important department. These textbooks, of the Senior Physician and Senior Surgeon, respectively, of the foremost of the Dublin hospitals, are both representative monuments of the professional skill and scholarly attainments which so characterize the authors of both.

Mr. McArdle chose for his lecture the subject of "Tuberculosis," and dealt with this crying evil with his usual boldness and originality of thought and precision of meaning. His views on notification and the value of sanatoriums have been warmly advocated by the lay press and are sure to bear early fruit. Indeed, the only faint flutter of discontent evolved by his lecture was the moodily-whispered one of some atrabilious physicians who insinuated that this brilliant operator, having conquered the world of surgery, seemed now about to invade one of the most important and fruitful of the physician's preserves. But it is safe to say that no such thought had entered the mind of the speaker.

Progress of Medical Science.

New York Medical Journal, November 17, 1906

Some Remarks on the Diagnosis of Typhoid Fever.—R. Stein thinks that diagnosis in this disease is still beset with difficulties. Precise diagnosis is not always possible. Typhoid cases present no difficulty. The difficulties have been augmented by the occurrence of the recent influenza epidemics. Some of the laboratory tests are confusing and misleading. Moreover, the surgical trend of practice has increased the practitioner's responsibility and anxiety. The sudden onset of indications may call for an exploratory laparotomy that reveals possibly a typhoid perforation, possibly an appendicitis or a suppurating gall-bladder. The author makes a plea for a more careful study of the temperature curve, for a close observation of the clinical ensemble, search for an enlarged and palpable spleen, and for the elimination in a suspicious case of a simple gastrointestinal infection. He discusses the combined toxemia of malaria and typhoid. He attaches most importance to the Ehrlich test. As to examination of the blood for bacilli, he notes that in just three cases in which we are in doubt the bacilli are not plenty enough to be demonstrated with any degree of certainty. The Widal test is satisfactory, but the author notes that in private practice it has served him as a means of proving diagnosis after it was otherwise established, rather than as an absolute sign. He considers the leucopenia as the most striking feature of typhoid blood. Another very striking characteristic is the regularity with which the eosinophile cell disappears in the course of the febrile run.

The Membrane and Complications of Diphtheria.—The paper of W. S. Cornell is largely a statistical study of 616 cases collected from Philadelphia municipal reports for 1905. Comparisons are also made with similar figures from other cities. Briefly, we may say that the tonsil (one or both) was involved in 456 cases. The membrane was limited thereto in 252. The larynx (including the trachea) was involved in 63 pure and 43 mixed cases. The nose was involved in 11 pure and 33 mixed cases. The pure pharyngeal cases numbered 28. It seems to be true that in growing children the disease is more apt to attack the larynx and nasal cavities, and that a marked tendency is shown by the membrane to spread from the part first involved and to attack the pharynx secondarily. Of the total 616 cases, 133 were classified as mild, 258 as of moderate severity, 184 as severe, 40 as septic, and 1 as gangrenous. In 579 cases definitely reported 432 were free from any special complication. The complications most frequently met with were these: Adenitis and cellulitis 66, neuritis 24, nephritis 21, myocarditis 19, pneumonia 10, scarlet fever 4, hemorrrhage from the nose 3. The mortality rate of the series is not given.

The Tuberculosis Problem in Prisons and Reformatories.—S. A. Knopf covers familiar ground in his paper which directs special attention to the high mortality rate from tuberculosis in institutions of the class named. He finds that it begins in the early environment of most prisoners who have in the majority of instances grown up under a distinctly bad hygienic environment. So far as early diagnosis is concerned, he calls attention to the fact that when bacilli are present in the sputum there has already begun a disintegration of lung tissue. The author does not believe in tuberculin as a diagnostic test, claiming that it has caused reaction in actinomycosis, syphilis, and anemia, and has reacted in cases in which there was no tuberculosis present. The paper closes with a plea for more sanitary conditions in prisons, and various suggestions are made with reference to lessening the amount of tuberculosis in prisons and reformatories.

Aids to Accuracy and Efficiency in Radiotherapy.—H. G. Piffard describes two instruments. The first is called an oscilloscope and consists of a vacuum tube nine or ten inches long, and an inch or more in diameter. Sealed into the ends are electrodes extending nearly to the middle, being sparated from each other by a gap of about a tenth of an inch. When the tube is connected to the terminals of the coil, and the current passes, a bright glow will surround the electrode nearest the negative side of the coil, while the positive terminal will be free from it. In a unidirectional current the glow persists on one of the terminals, but as the coil current is alternating we find in practice that for an inch or more both terminals will glow, due to the fact that they each in turn become negative, and the alternations are of such frequency that the eye cannot separate them. The extent of the flow may be approximately equal on each side, or one may be much shorter than the other. The fact of the double glow indicates the existence of the inverse current. The second device is known as the Villard valve, the action of which is based on the fact that the positive current flows readily in a vacuum from an electrode of small surface to one having a surface very much larger, but will not flow readily or at all from a large surface to a small one. In this way the inverse is choked off or quenched. If the valve should for any reason prove inefficient the oscilloscope detects the fact; and all valves should from time to time be tested with it. The valve then inserted in series with an *x*-ray tube rectifies the current, and renders it unidirectional, and the milliampèremeter will give a true reading, and indicate the amount of energy expended in generating the rays. In using the valve it is fully as important to maintain a uniform vacuum as it is with the focus tube. The original Villard is furnished with a platinum osmoregulator which may require attention several times during a single exposure. The author prefers a modified form (figured in the paper) in which the regulation is automatic. The vacuum should be a mean between a Geissler and a Crookes. The appearance of a green fluorescence in the tube indicates that the vacuum is much too high. A thoroughly efficient outfit, then, will comprise not only a coil and tube, but also a valve and a milliampèremeter, together with an oscilloscope to act as a detector of an inverse current.

Journal of the American Medical Association, November 24, 1906.

The Causation of Ground Itch (Uncinariasis).—C. A. Smith has been able, by using pure cultures of the larva of *Uncinaria americana,* to make an alcoholic extract from them that is very irritating to the skin and produces the symptoms of a mild type of ground itch. The mildness of the symptoms, he thinks, may be due to the fact that the application was made externally and only once in each case, while in the true form the larvæ penetrate beneath the surface and continue there to give out their irritating secretion. The substance causing this eruption has not yet been obtained in sufficient quantities to be recognizable. It appears to act somewhat as the poisonous principle of poison ivy. Extracts made with ether or simple water produce no symptoms. The control experiments with absolute alcohol were likewise symptomless. The article is illustrated.

Paralysis Without Gross Anatomical Change.—J. H. W. Rhein gives the histories and pathological findings in seven cases of paralysis associated with chronic kidney disease, such as are not infrequently regarded as of uremic origin, gross anatomical lesions being wanting. The microscopical examination revealed the lesions of probable or possible syphilitic disease of the brain in all the cases, round-cell pial infiltration and vascular thickening, etc., but in two of the cases minute patches of softening in the paracentral region were discovered. Rhein believes that such patches, undetected by macroscopical observation, are often the cause of hemiplegias reported as not associated with gross anatomical changes. Another cause which should not be overlooked in these cases is syphilis, and he emphasizes the importance of careful and extensive histological studies of the brain and spinal cord before excluding demonstrable lesions, in reporting these cases. The perivascular distention which is extensive in some of the cases may also, he thinks, play its part in the production of the transitory paralyses that are observed.

Affections of the Spinal Cord in Epileptics.—W. N. Bullard gives the results of his examinations of over 500 patients in the Massachusetts Hospital for Epileptics. He found evidence of spinal cord disease in a small number. In certain proportion it was only a coincidence, but in a far larger proportion the same cerebral lesion produces the symptom-complex of epilepsy and the secondary degeneration of the spinal cord. We would naturally expect to find secondary degeneration of the cord in epileptic hemiplegia, and he states that we occasionally find other spinal affections, possibly also secondary to cerebral lesions. In the third class of cases the primary pathological cause of the convulsions acts directly on the spinal cord as well as on the brain, and in such cases one can be primary as well as the other. It is probable, he says, that in typical idiopathic epilepsy, lesions can be found in the cerebrum or cerebellum in practically all cases when properly examined, and he believes that similar lesions can be detected in the spinal cord, though definite evidence is still lacking. In conclusion, he remarks that, since writing the above, he has heard from Dr. Southard that microscopical examination of spinal cords from epileptics have given interesting results. Marchi degenerations of a diffuse nonsystemic character were found in almost every case of the series examined.

Faucial Tonsils.—Charles M. Robertson presents some observations made in the last few years on the entrance of tuberculosis into the general system with special reference to the faucial tonsil. He describes in detail the anatomy of this structure and its relations to other parts. He relates his researches, and in regard to infection states that if the surface membrane were the point of entry we should find tuberculous changes here. This he has never seen in the slides examined. It has always been in the crypt. The crypts which empty into the throat direct are seldom if ever affected. Those emptying below the middle of the gland were not affected in a single instance. The greater number of infections were from crypts emptying into the supratonsillar fossa. The part of the crypt affected is universally in its deeper extremity where giant cells are abundant in the tuberculous tissue. A few giant cells were at times noticed along the beginning of the crypt, but in these sections they were less in number than in the deeper part of the crypt. The cells were found dispersed in the tissue as far as the trabeculæ which seemed to limit the spread of the tuberculous change. When the gland is diseased, he says, it is important that it be enucleated completely, and that pockets in the soft tissues around the tonsils must be destroyed. He describes his treatment and technique and discusses accidents liable to occur during and after operation. The article is fully illustrated.

The Odor Test in Middle Ear Suppuration.—H. Gradle calls attention to the value of the odor test as a guide in the conservative treatment of ear disease. If the odor quickly disappears with washing out with water, followed by boric acid applications, the disease is evidently superficial and requires no operation. Even when small areas of caries exist this treatment may sometimes suffice, though perhaps more time or some modification may be needed. When irrigation followed by boric acid applications fails to remove the odor within a few days it is useless to continue it. Intratympanic irrigation will occasionally succeed in dislodging pent-up pus or retained epidermic scales, whereon the odor disappears and the now accessible focus of suppuration heals, but not very often. In a certain number of cases the suppurating source is so inaccessible that these methods all fail to remove the odor of decomposition. The only successful conservative treatment for these cases in Gradle's hands has been careful tamponing with gauze, introducing narrow strips of good absorbent gauze, after proper cleansing, into actual contact with the source of the pus as far as it is visible. The efficiency of the method depends upon the dryness of the gauze and hence its frequent replacement. The improvement is slow, it is never less than three weeks, and often over six, before the gauze remains dry. The odor may persist till there is absolutely no secretion or it may cease when it has been reduced to a minimum, when suppuration often ends within a few days. Treatment by gauze drainage ends in a complete cure (50 per cent. of cases), partial cure (33.3 per cent.), or failure (16 per cent.). If properly done tamponing does not distinctly lessen the discharge within three weeks, and continue to reduce it, no ultimate benefit can be expected and operation only will succeed. As partial cures Gradle reckons those cases in which the drainage removes the odor but fails to stop completely the suppuration, a trace being left. He hesitates to recommend operation in these cases of partial success. With due care the patients get along without serious consequences, and in his experience the disease has lost its progressive and hence dangerous character when the odor has disappeared.

Constitutional Low Arterial Tension in Children.—L. F. Bishop calls attention to a condition observed in children, of constitutional low arterial tension, probably of nervous origin, though the symptoms are circulatory. The pulse in these cases would suggest in others the prostration of acute or chronic disease, but the condition is habitual, there are no heart lesions or cardiac symptoms, and the kidneys act normally. The defect seems to be in a lack of the normal back pressure in the peripheral circulation, the blood circulates too easily. To differentiate such a case from cardiac weakness one need only make a demand on the circulation by active exercise or observe the response in the case of acute disease. Such children suffer much discomfort from lack of circulation, as by cold feet, depression, constipation, and skin disorders. They are also subject to catarrhal disorders, but they thrive on active exercise and on every sort of mental and physical exercise that stimulates the circulation. Very hot baths of short duration benefit them, but they do not respond well to cold baths. Though the class is not a large one, the cases are sufficiently numerous to be met by every pediatrist. The importance of recognizing the condition lies in placing it where it belongs, and not seeing in it the accompaniment of a supposed anemia or cardiac disease or a sequel of some local disorder. It is a condition that must be met by a proper regimen, and is one that has a tendency to improve or even to disappear after adolescence. Its proper recognition will relieve anxiety on the part of the family physician; it is not a true failure of the circulatory apparatus resulting in an inability to respond to the demands for pressure, nor is it due to the exhaustion from prolonged high arterial tension. This latter, secondary low arterial tension, is rare in children.

The Lancet, November 10, 1906.

Adolescent or Late Rickets.—H. H. Clutton gives the clinical histories of three cases and furnishes an illustrative plate. He thinks the disease is practically the same as infantile rickets modified in some respects by the age of the patient. Is the adult form a continuation of the infantile or an entirely fresh development? The author declares that in many (not all) instances he is inclined to regard it as a distinct development.

On this supposition, therefore, we must assume that rickets may arise at any age from infancy to adolescence. The causes at work all tend to produce the same changes in the bones. Although we naturally attribute to diet the main responsibility for infantile rickets, we do not deny the influence of the hygienic surroundings of the patient's home. In fact, whatever interferes with metabolism of the body would be likely to prevent the normal development of the bones. One of the most important of these influences upon metabolism must be the higher nerve centers which, unimportant in infancy, are quickly developing toward the age of puberty. We must therefore acknowledge that new factors arise which are scarcely present in infancy, and which are of as much importance as food, if not more. The period of from 12 to 14 years of age is a time of great intellectual stress from the educational point of view, and anyone who has seen much of children will know what this may mean to many. In some children the competition of school life may produce all sorts of nerve trouble, from insomnia and night terrors to epileptiform convulsions or facial distortion and mimicry. The same intellectual strain and competition will continue throughout the adolescent period of life or even longer. This is more important than diet at this age, for if it be a cause of this trouble it is difficult to eliminate, and accounts perhaps for the long continuance of the adolescent cases. It is noticeable that in two of the patients diet can have had but little influence as they were the children of fairly well-to-do parents. In the first case there is evidence of prolonged mental strain during school life, and in the second the patient had reached the sixth standard of the board school at from 12 to 13 years of age. The latter fact perhaps only proves that she was not a backward child. No special treatment is applicable to the adult form.

Stokes-Adams Disease, and Cardiac Arrhythmia.—J. Hay and S. A. Moore present a final report on a case of bradycardia and heart-block first exploited in the *Lancet* of January 20 of the current year. Full autopsy records are given, together with various charts showing the variations in conductivity and pulse frequency. The interesting feature is that they have been able to record a case of Stokes-Adams disease in its second stage—that is, in the stage of syncopal, apoplectiform, or epileptiform seizures. These seizures were of all grades of severity and tended to occur in groups with periods of comparative comfort intervening. The advent of seizures was usually indicated by definite prodromal symptoms. The necropsy revealed partial obliteration of a certain nerve bundle which would cause a persistent depression of conductivity. An analysis of numerous tracings revealed marked variations in conductivity, all grades from normal conduction to complete heart-block being in evidence at one or another time. This suggests influences in addition to the organic lesion. Such influences were probably nervous in character and affected conductivity either directly through the vagus or indirectly by altering the auricular frequency.

Erythema Autumnale.—J. C. Thresh refers to a dermatosis, called also harvest rash or prurigo du Rouget, due to a parasite living on the ordinary harvest spider. Méguni has described the parasite, regarding it as the hexapod larva of the silky trombidian (*Trombidium holosericeum*). The larval form is so small as to be barely visible to the naked eye, but being of a brick-red color masses of them are easily distinguishable. They apparently breed upon plants, but when opportunity occurs transfer themselves to man or animals. They chiefly attack persons with delicate skins and seem to prefer the legs and inner side of the thighs, but may reach any part of the body. From the legs they very quickly travel to the upper parts of the body unless their progress is arrested by some tight article of clothing. The base of the downy hairs attracts them, and here they attach themselves by their formidable-looking claws and insinuate their suckers under the epidermis or into the glands at the base of the hairs. The abdomen of each larva then gradually distends until it is four or five times its original size and becomes visible as a bright red dot. The itching produced is so intense that the patient cannot rest. The skin swells, becomes red, or sometimes even violet, around the points attacked. These points, which may be a centimeter in diameter, are always discrete and usually have a central projection of appreciable size. Sometimes the eruption is distinctly papular or vesicular, and if rubbed may become pustular. This malady seems especially common in France, where benzine is used to kill the parasite and warm baths or dilute vinegar to allay the irritation. If a part has been affected where benzine could not be a safe application, as the eyelid, the parasites may be dislodged by a fine needle.

The Treatment of Laryngeal Tuberculosis.—H. Barwell discusses the limitations of local treatment in this disease. He notes that when the accompanying pulmonary lesion is so far advanced or so rapidly progressing that a restoration to some degree of health and comfort cannot be looked for, the treatment of the laryngeal affection should be entirely symptomatic; that where there are no severe symptoms it is both useless and cruel to submit the patient to active treatment either with cutting instruments or strong caustic pigments. Such cases make up a large proportion of all the cases of tuberculous laryngitis which come under his care. He finds that antiseptic and caustic pigments are of great value in promoting the healing of ulcers and the shrinkage of granulations, but they have little or no effect on massive infiltration lying beneath unbroken epithelium; they must be applied under guidance with the mirror on a strong cotton-wool mop and must be thoroughly and forcibly rubbed into the affected parts. The secret of success lies in their proper application, and a light painting on of pigments is of little use. Among the many drugs employed in this way lactic acid still holds its place; it must be used in sufficient concentration, and for some time he has employed almost exclusively a mixture introduced by Lake consisting of lactic acid 50 per cent., formalin 7 per cent., and carbolic acid 10 per cent. No local anesthetic is necessary before the application of pigments; the frequent use of cocaine has a most harmful effect on the appetite and the general health. At the most in very irritable cases a little 5 per cent. solution of cocaine to the pharynx may be employed until the patient becomes used to the manipulation. Before surgical operations thorough anesthetization is necessary. For this purpose he sprays a little 10 per cent. cocaine on to the pharynx and then from a curved syringe guided by the mirror drops a little of the same solution on to the epiglottis and on to the part to be operated on; after an interval of five minutes he repeats this, and after a similar interval performs the operation. In this way the cocaine is only applied where it is wanted and, very little being used, he has never seen bad effects; the method is pleasant to the patient and does not cause coughing or irritation.

British Medical Journal, November 10, 1906.

Improved Methods for Recognition of Blood and Seminal Stains.—E. H. Hankin considers this question with special reference to tropical climates. In such climates if the stains are kept moist they putrefy rapidly; if kept dry they become so insoluble as to react with difficulty in ordinary reagents. The author therefore adopts for blood stains the following procedure: If on clothing, etc., the suspected stain is cut out and plunged into boiling water for a few moments. It is then placed on a glass slide and wetted with ammonium sulphide. It is examined under the microscope, and the specimen is moved until the whole field of view is occupied by a portion of the colored material. If this cannot be achieved with a low power, the use of an oil immersion may be necessary. The eyepiece is then taken out and replaced by a microspectroscope. If the stain is of blood the two absorption bands of hemochromogen will be seen. Should the bands not be visible—as may occur, apparently owing to the effects of commencing putrefaction—a drop of a 10 per cent. solution of potassium cyanide should be allowed to fall on the stain. Two bands will at once develop resembling those of hemochromogen, but situated a little nearer to the red end of the spectrum. The object of boiling the blood-stained cloth is to prevent the coloring matter from going into solution. In case of seminal stains, the following rules are given: (1) The suspected stain is boiled for two minutes in a watery solution containing tannin ½ per cent., and sulphuric acid 1 per 1,000; (2) the stain is washed for two minutes in a solution made by adding one part of saturated ammonia solution to 400 of water; (3) it is then transferred for two minutes to a 2 per cent. solution of potassium cyanide; (4) it is then rapidly washed in distilled water, scraped, and teased up on a glass slide, dried, fixed by heat, and stained.

Tetanus in Two Brothers; Subdural and Subcutaneous Injections of Serum; Recovery.—Detailed histories of the cases are given by J. Adam. Case I was that of a man of 29 years who had been thrown from a van and dragged along the road, receiving several dirty

wounds on the head, hands, and legs;tetanus symptoms on tenth day; serum began on the eleventh day, finished on twenty-second day; two subdural injections. Total amount injected 157 cm. Case II was that of a farmer with a slight bruise of the great toe; first tetanus symptom on third day; muscles of jaw and spine chiefly involved; serum first injected on the seventh day (subdural), last injection on fourteenth day. Total amount 100 cm. Wound swabbed out with pure carbolic on seventh day, but required no further dressing.

Quinine Hemoglobinuria or Blackwater Fever.—A. D. Kelcher reports the case of a man of 28 years who was suffering from chronic malarial poisoning and in whom the administration of quinine presented the invariable sequence referred to in the title. Reference is made to other similar cases on record. One and one-half grains of quinine would cause hemoglobinuria to appear in two hours. The indications for treatment of the case reported were perfectly clear, and simply consisted in stopping the administration of the quinine, which was so evidently the exciting cause of each attack, and if the quinine is the exciting cause in all cases, the continued administration of this drug seems quite irrational and productive of nothing but harm. In this case, within twenty-four hours of the commencement of the attack, the urine had again become its natural color, the jaundice had almost disappeared, and the temperature was only slightly above normal. If repeated doses of quinine had been given the patient's symptoms would have been intensified instead of disappearing, and from the gravity of the condition after single doses it would have been easy to foresee a fatal termination had the original cause of the attack been frequently repeated over a short period of time.

Münchener medizinische Wochenschrift, November 6, 1906.

Sarcoma of the Epicardium.—Schöppler reports a case of this variety of new growth occurring in a woman of seventy-three years. The heart weighed 680 g. and there were metastases in the left adrenal body. As the result of a review of the literature he was able to find recorded only four cases of primary new growths of the pericardium and only sixty cases of primary tumors of the heart. Of these twenty-nine were in men, fifteen in women, and in seventeen cases the sex of the patients was unknown. He concludes that new growths of the pericardium are among the rarest of neoplasms and that of tumors of the heart fibroma and myoma are the most frequently seen and sarcoma has the second place. Tumors of the heart and the pericardium are usually connective tissue tumors, and most often originate in the left auricle. Men are oftener attacked than women, and the age of the patient has little bearing on the etiology. New growths of the heart do not present any characteristic clinical picture.

The Occurrence of Endocarditis in Muscular Rheumatism.—Bechtold, like Leube, is of the opinion that muscular rheumatism as well as the articular variety is an infectious disease, and gives as his reasons for this belief its occurrence in epidemics, the elevation of temperature that is frequently observed, the general constitutional disturbance, and the complication of endocarditis that is present in many cases. In an epidemic observed by the author during the past summer endocarditis was present six times, whereas in 902 cases observed since 1893 endocarditis was noted only eleven times. The author considers that this fact of the greater tendency to endocarditis in some epidemics than in others is an argument in favor of belief in the infectious nature of the disease, for variations in the frequency of certain complications in different epidemics form a characteristic of many infectious diseases. Leube has suggested that the infectious agent of muscular rheumatism, if not simply the attenuated virus of articular rheumatism, may be at least closely related to it, but apparently the two are not identical.

Deutsche medizinische Wochenschrift, November 8, 1906.

The Use of Carbolic Acid in the Treatment of Buboes and Furuncles.—Wolff writes very favorably of the use of concentrated carbolic acid in the treatment of inflammatory conditions such as buboes, carbuncles, furuncles, etc. The acid used for this purpose, he says is preferably a concentrated solution of the crystalline acid in absolute alcohol in the proportion of nine of the former to one of the latter. The acid liquefied with alcohol is said to be more effective than when water is used. If the bubo, for example, is not fluctuating, a small amount of the acid is painted on the overlying skin every day for three or four applications until the skin begins to desquamate. Several days are allowed to elapse without treatment, and then, if necessary, the applications are repeated. Fluctuating buboes receive two or three applications of the acid and on the fourth day are incised sufficiently to allow the contents to escape. The abscess cavity is swabbed out with the acid and this is repeated at intervals of two or three days until a granulating wound results. Furuncles if of only moderate severity are treated by dabbing on small amounts of acid, but if they are large, or already give evidence of breaking down, it is necessary to work the acid into their interior through either an already existing natural opening or through a small incision. In many cases a central canal can be discovered through which it is possible to introduce the acid by means of a fine probe. This method is said to be just as effective but much less painful than the old plan of injecting the acid into the depths of the lesions by means of a hypodermic needle. The author also recommends carbolic acid applied in a similar way in the treatment of aphthous and ulcerative stomatitis, scrofuloderma, and tuberculous glands.

The Effects of Nicotine Injections on the Aorta of the Rabbit.—Adler and Hensel describe the lesions produced in the vascular system of the rabbit as the result of intravenous injections of nicotine. One and five-tenth milligrams of the drug were injected at a time and it is stated that after thirty-eight injections in most cases demonstrable changes are present in the aorta. These comprise necroses of the circular muscular fibers of the media, which are partly localized and partly cover considerable areas. The degenerated muscle cells become calcareous, but fatty degeneration was not observed. In consequence of this weakening of the arterial wall the elastic fibers stretch and become dilated so that the lumen is increased in size. The necrosis and calcification are confined to the media, but where dilatation of the vessel results a marked proliferation and thickening of the itima also occur. While these lesions are not exactly comparable to those of arteriosclerosis, the authors consider that they are of importance in regard to the theory of aneurysm formation and they hope that their prosecution will throw help to clear up the difficult problems of human arteriosclerosis.

French and Italian Journals.

Paralysis of the Abducent Nerve During the Course of Otitis.—M. Terson and M. A. Terson speak of the development of persistent diplopia accompanied by all the signs of ocular muscular impotence in children during the course of a purulent otitis. In such cases parents and physicians fear a fatal termination either by meningitis or by thrombophlebitis of the intracranial venous sinuses. Nevertheless, ocular motor paralysis is not always a precursor of grave complications. Sometimes occuring by itself, at other times accompanied by optic neuritis, the affection goes on to recovery. The writers have observed two cases of this nature. They conclude from their investigations that there may exist a paralysis of the abducent nerve which develops during a suppurative otitis media and which may occur by itself or which may be accompanied by optic neuritis. In several cases this complication has not had a serious termination either in relation to life itself or in relation to vision, but has been completely cured. It is very probable that such a condition is not associated with a reflex disorder, but with a condition of infection; and that the various anastomoses, venous and lymphatic, which associate the sixth pair of nerves with the middle ear through the medium of the carotid and the carotid canal, play a rôle which explains the relative frequency of this complication.—*Archives médicales de Toulouse,* June 15, 1906.

Resistance of the Virus of Rabies to Putrefaction.—Tullio Mazzei has observed that the brains of rabid animals preserve their virulence even after putrefaction has set in up to three weeks after death. The author has made experiments on partially putrefied brains sent to the laboratory for examination. He finds that by the method of filtration the virus may be used for inoculation into the peritoneum of animals and will prove virulent. If the method of preparation with glycerine was used the material would be worthless for purposes of examination and diagnosis. The period of incubation is much elongated, and this depends on the diminished virulence of the germs. Negri's bodies resist putrefaction for a long time and may be recognized for ten days, while the material remains virulent up to forty days. This method is of great value in enabling organs that have undergone putrefaction to be successfully examined.—*La Riforma Medica,* September 22, 1906.

Book Reviews.

A Short Practice of Medicine. By Robert A. Fleming, M.A., M.D., F.R.C.P.E., F.R.S.E., Lecturer on Practice of Medicine, School of the Royal Colleges, Edinburgh; Assistant Physician, Royal Infirmary, Edinburgh. London: J. and A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1906.

The author apologizes for bringing out another Practice of Medicine, knowing that there are many in the field. He justifies his work, however, by claiming that a shorter treatise will be found of use in preparing for examinations and as a help in clinical lectures.

A weeding-out process has been employed in order to make the book of practical size; for instance, the examinations of the urine and stomach contents and sphygmographic tracings are omitted, the reader being expected to refer to special treatises on clinical and laboratory methods. The skeleton of this volume is much like other works on the subject, starting with the infectious diseases, constitutional ailments, intoxications, parasitic diseases, diseases of the various systems, and concluding with a very excellent one of two hundred pages on the nervous system. This last section has some well-chosen and instructive plates and will prove a valuable synopsis of the present knowledge of these diseases.

If we were to criticise any one feature it would be that the paragraphs on treatment are too brief and not helpful enough. In the technique of typhoid bathing no mention is made of the all-important surface friction and the expressed fear of collapse and cyanosis would indicate that surface rubbings were probably insufficient when performed by English nurses. As a whole, the book is full of concise information, up to date, sound in its teachings, following the conservative methods, clear though concentrated, and as a shorter treatise it will surely find a place, particularly in the hands of students.

Phlebitis and Thrombosis. The Hunterian Lectures for 1906. By Warrington Haward, F.R.C.S., etc. New York: William Wood and Company, 1906.

This book constitutes a valuable addition to the literature of the subject, containing as it does not only an excellent résumé of what is known in general on the subject, but also the writer's own observations, particularly as regards the remoter effects of the lesion. In connection with this attention is directed to the treatment of the condition, the main point being that in cases in which a vein becomes obstructed by a thrombus, the collateral circulation should be developed in the deep rather than in the superficial veins. The work presents an excellent and valuable summary of the subject within the limits of a comparatively small number of pages.

The American Illustrated Medical Dictionary. A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and the Kindred Branches, with their Pronunciation, Derivation, and Definition, Including much Collateral Information of an Encyclopedic Character. By W. A. Newman Dorland, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital; Editor of the American Pocket Medical Dictionary; Fellow of the American Academy of Medicine. Together with New and Elaborate Tables of Arteries, Muscles, Nerves, Veins, etc.; of Bacilli, Bacteria, Diplococci, Micrococci, Ptomains and Leukomains, Weights and Measures; Eponymic Tables of Diseases, Operations, Signs and Symptoms, Stains, Tests, Methods of Treatment, etc. Fourth Edition. Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1906.

This is the most compact and easily handled of all the unabridged medical dictionaries in the market, yet it is not lacking in completeness, for a careful test made with a list of the most recently born medical terms has shown very few absent. The type is small but distinct. The definitions are in general excellent—concise, yet comprehensive, clear, and accurate. In these respects Dorland's dictionary is worthy of the highest commendation, and is the equal, if not the superior, of its rivals. But the editor stumbles badly and sometimes falls flat in his spelling and pronunciation. His spelling is inconsistent. For example, he insists upon leukocyte, yet spells leuconostoc with a *c*, although both are derived from the same word, λευκός; he writes catabolic, but karyokinesis, although both are derived from Greek words, with initial κα. The convenient distinction made by the United States and British Pharmacopœias between alcaloids and glucosides in spelling the former with and the latter without a final *e* (morphine, salicin) is ignored in this dictionary. Indeed, throughout the work there is apparently no rule for spelling, and no recognized authority is followed except the editor's personal preference, which the reviewer finds too uncertain to recognize as authoritative. It is not even Rooseveltian. The same may be said regarding the pronunciation. Syncytium is pronounced here sin-sish'e-um, but syncytiolysin, sin-sit-e-ol'is-in; opponens is accented on the antepenult in utter disregard of Latin quantity and English usage; Pfeiffer and Pflüger are prematurely turned into English cognomens, the initial *P* being ignored in the pronunciation; thermometer is correctly accented, but motormeter is accented in the first syllable, though in motorpathy the accent is placed on the second syllable. As regards spelling and pronunciation this dictionary is an unsafe guide; but in respect of definitions (after all, the most important consideration in a medical dictionary) the work can be confidently recommended. In a progressive science, in which the coinage of new words is so active as it is in medicine, the latest edition of any standard dictionary must of necessity be the most complete for the time being, and so we can say that the fourth edition of Dorland's Dictionary is at the present writing the best.

The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery under the general editorial charge of Gustavus P. Head, M.D. Vol. VI. Series 1906. General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, M.D., Professor of Medicine, Chicago Clinical School. Chicago: The Year Book, Publishers, 1906.

In this volume, the sixth of this useful series of year books, is included Part II. of General Medicine. The subjects covered are typhoid fever, malaria, yellow fever, relapsing fever, malta fever, beriberi, dysentery, and diseases of the mouth, stomach, intestines, liver, pancreas, and peritoneum. An appendix on abdominal and epigastric pain and on tuberculosis of the thoracic duct is added. The work of compiling and editing this volume has been done with great care and good judgment, and it forms a worthy addition to the other volumes of the series already published.

Elements of General Chemistry with Experiments. By John H. Long, M.S., Sc.D., Professor of Chemistry and Director of the Chemical Laboratories in the Northwestern University Medical School. Fourth Edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1906.

This is not a textbook on chemistry, but is essentially a book of experiments for use in the laboratory. As such it should serve a useful purpose, the experiments being numerous and well selected. In this edition there is a new chapter dealing with the theories of solution and the conditions of chemical equilibrium, both of which topics are dealt with in a brief, but clear and satisfactory manner. The book is well worth the attention of teachers.

Commentarii di Clinica Moderna desunti della Morfologia del Corpo Umano. Pel Prof. Achille De Giovanni, Direttore della Clinica Medica Generale della Regia Università di Padova, etc. Parte Speciale. Milano: Ulrico Hoepli, 1907.

In a preceding volume, the "General Part" of the present monograph, Professor De Giovanni described the fundamental principles of "clinical morphology," as he styles his subject, and considered the methods of scientific diagnosis. De Giovanni's work emphasizes, as its title implies, the value of morphological considerations in the study of clinical data. The young physician should be so drilled in his morphology, in his knowledge of the relative positions, measurements, and structure of parts, as to be able to note without measurements any deviations from the normal. Somatometry must be used, however, when more precise data are needed. The present volume, the first of those intended to cover the special part of the subject, is devoted to the study of the "clinical morphology" of the abdomen. A great variety of subjects are considered, and it would be impossible to review these essays in full. The morphological relations of the abdominal circulation of venous and lymphatic plethora, of "abdominal scrofula," etc., are considered in the first two chapters. Next the pathology of the ascending vena cava and that of the liver and the spleen are treated in a series of essays. The subjects of "idiopathic hematuria" and the "lymphatic kidney" giving rise to a physiological albuminuria are discussed in two chapters, while the closing essays are devoted to primary pancreatic cancer and to "gynecological notes." Professor De Giovanni's monograph is written in fascinating, easy, and personal style, which renders it worth reading in hours of relaxation. His ideas in many respects are original, and he displays throughout that wonderful gift of teaching and of clinical observation which, unfortunately, is so rare in these days.

Society Reports.

DELAWARE STATE MEDICAL SOCIETY.

Annual Meeting Held at Wilmington, Tuesday, October 9, 1906.

PRESIDENT, DR. JOHN PALMER, JR., OF WILMINGTON.

THE meeting was opened with prayer by the Rev. William Fred D. Lewis, Wilmington. An Address of Welcome was delivered by the Hon. LEVIN IRVING HANDY. In the course of this address the speaker referred to the spirit of jealousy that existed among the members of the profession, due largely, he believed, to the fact that they were so segregated in their work, and believed that closer association would do much to eradicate this feeling. He urged the enactment of laws requiring both a higher preliminary education and a longer course in medicine as a prerequisite to its practice.

The President's Address.—Dr. JOHN PALMER, JR., of Wilmington, in his address, reviewed the progress of medicine and surgery and the establishment of medical schools, hospitals, etc. He favored the present tendency to give less medicine and improve the sanitary and hygienic conditions, and cited approvingly among recent acquisitions to the relief of disease, the open-air treatment of tuberculosis, the *x*-ray, etc. He felt that the specialist should have a foundation of some years in general practice.

Early Diagnosis of Tuberculosis.—Dr. A. ROBIN of Wilmington, in this paper, remarked that until recently this disease had been looked upon as necessarily fatal. The susceptibility varied with the individual and treatment should be directed toward increasing the resistance and nutritional power of the patient, careful regulation of the diet and mode of life being essential factors. Anatomical or physiological defects might form a predisposition to the disease. The most valuable diagnostic signs were rise of temperature in the afternoon, loss of appetite and weight, weakness, dyspnea on exertion; in the absence of sufficiently marked signs to warrant a diagnosis the tuberculin test might be resorted to. Microscopical examination frequently would not show the tubercle bacilli until late in the disease, and while the tuberculin test was difficult of application in private practice, it was generally reliable. In conclusion, he again urged the early diagnosis of the condition, and expressed the opinion that this, with proper supervision, would, in time, eradicate the disease.

Dr. PETER W. TOMLINSON of Wilmington said that, if tuberculosis were recognized in its incipiency, it would be well to advise the patient to pursue that life which was demanded for the betterment of his condition, and even in cases of doubt it was perhaps better to give the patient the benefit of the doubt and advise such measures. He remarked on the treatment, particularly the giving of less medicine and life in the open air, believing that more depended upon proper nourishment, fresh air, and hygienic measures than the giving of drugs.

Dr. PHILIP MARVEL of Atlantic City, N. J., referred to the necessity for more thorough primary physical examinations, repeated at short intervals, in suspected cases, in order to determine the presence or absence of the disease in its incipiency, when treatment would be of the most avail. In regard to tuberculin, notwithstanding the authorities Dr. Robin had cited as to the fact that it was not harmful, he said that there was a feeling against its use.

Dr. Robin, in closing, stated that he had gone carefully over the literature of the subject, and that he had yet to find a single adverse criticism of the use of tuberculin. He referred to its use at the Johns Hopkins Hospital and other institutions, and considered it no more harmful than any other powerful drug, and that no more harm would come from its use for diagnostic purposes than from the diagnostic use of quinine in malaria, or iodide of potassium in syphilis. He believed, however, that the matter should be carefully explained to the patient and the possibility of danger revealed to him, and when this was done he thought they would as willingly take the risk as they would that from an anesthetic or an exploratory laparotomy.

Some Remarks on Gastric Ulcer.—Dr. H. A. CLEAVER of Wilmington stated that there were few diseases of the gastric tract that exceeded in importance gastric ulcer. Social history, occupation, climate, or nationality appeared to have but little influence, although there did seem to be a slight predisposing influence among workers in glass, metal, and porcelain. The pyloric region was thought to be the most susceptible to this condition, and among the predisposing factors were mentioned embolism, thrombosis, venous stasis, interstitial hemorrhage, ecchymosis of the gastric mucosa, etc. He discussed as causative factors, the infectious diseases, such as typhoid fever, puerperal fever, etc., and also the theory of its causation by self-digestion, in consequence of lessened resistance in the walls of the stomach, or increase in the digestive activity of the gastric juice. The differential diagnosis between gastric ulcer and carcinoma, erosion, duodenal ulcer, hysteria, gallstone colic, etc., was discussed in detail. He referred to the various kinds of medical treatment that had been recommended and contrasted them with the operative procedures of pyloroplasty and gastroenterostomy.

The Necessity for Careful and Accurate Diagnosis.—Dr. E. S. DWIGHT of Smyrna deprecated the practice of jumping at conclusions, or the frequent diagnosis of a disease which happens to be the practitioner's particular hobby. Vague terms should not be employed, but the physician after a thorough examination should decide definitely upon the conditions present. Uranalysis and examination of the vagina and rectum should, whenever necessary, be resorted to, and he believed that they were very valuable aids in many cases.

Anesthesia; with Report of Five Hundred Cases.—Dr. ARNOLD L. SPRINGER of Wilmington read this paper, in which he said that ether was used in 88 per cent. of the cases and chloroform in the remaining 12 per cent.; 2 per cent. of the former being started with chloroform. The average amount of ether administered was 2½ ounces; the average time under ether was fifteen minutes; vomiting occurred in 25 per cent. of the cases. He believed that the vomiting was due to the direct action of the ether on the stomach, as it did not occur when the anesthesia was produced by chloroform. Oxygen was necessary in 4 per cent. of the cases, and the return to consciousness was more rapid in these cases than when no oxygen was employed. He believed that the use of oxygen with any anesthetic eliminated a large percentage of the danger. In 75 per cent. of the cases the anesthesia was for major operations; no patient died from the effects of the anesthetic, and in most of the fatal cases the patients were *in extremis* when they were placed on the table. Urinary examination was made both before and after the anesthesia. Chloroform, he stated, was more dangerous than ether, especially in the hands of the inexperienced. In all cases there should be a thorough examination of the heart, lungs, and kidneys prior to operation, and in cases of threatened death artificial respiration should be resorted to.

Dr. A. ROBIN of Wilmington remarked that in looking over the reports of the State Board of Health he noticed that in a large number of death certificates the cause of death was put down as anemia, cyanosis, etc. He called attention to the fact that these were merely symptoms and not distinct conditions. Another frequent cause given was catarrh, without telling what organ was affected. This, he said, could indicate but one thing—carelessness in making the preliminary examination and diagnosis. In regard to ulcers of the stomach, he felt that the best way to diagnose this condition and to differentiate between it and gastric

carcinoma was to give the patient a test meal, consisting of a shredded wheat biscuit and a glass of water. At the end of an hour he gave a solution of bicarbonate of sodium of some standard strength, and then by listening with the stethoscope or phonendoscope, while the patient was swallowing and noting the ebullition which occurred, and the length of time it continued, one could determine approximately the amount of hydrochloric acid present.

Resolutions deprecating the fact that the newspapers permitted the advertisement of irregular physicians and quack remedies were presented, and it was decided that the Secretary should communicate with the various newspapers, calling their attention to the improper publications and requesting their discontinuance.

Dr. Emery Marvel of Atlantic City, N. J., referred to the action of the New Jersey State Medical Society in regard to the use of nostrums, and felt that the action of the lay papers, particularly *Collier's Weekly* and the *Ladies' Home Journal*, in exposing these remedies, had been productive of good results. He recommended that the Delaware State Medical Society express an official opinion in regard to this matter. He also referred to the endeavor of the New Jersey State Medical Society to increase the fees for life insurance examinations, and stated that the subject of contract practice had been taken up and condemned by this society.

The society passed resolutions endorsing the bill to be presented to the coming session of the Legislature, increasing the requirements for a license to practise medicine, and also the work of the Delaware Tuberculosis Society.

Officers.—The following officers were elected: *President*, Dr. John W. Clifton of Smyrna; *First Vice-President*, Dr. Frank L. Springer of Newport; *Second Vice-President*, Dr. Luther S. Conwell of Camden; *Secretary*, Dr. George W. K. Forrest of Wilmington; *Treasurer*, Dr. William G. Winner of Wilmington.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 2, 1906.

Dr. Samuel Lloyd in the Chair.

Primary Tumor of the Trachea. Extirpation.—Dr. Elsberg presented a patient ten years of age, upon whom he had operated on May 30, 1906, and removed a fibroma of the fourth and fifth rings of the trachea by splitting the trachea. The patient was a little girl who had had increasing difficulty in breathing for three months. When she was admitted to the hospital she was examined by Dr. E. Mayer, who reported that the patient had a broadly adherent tumor springing from the posterior wall of the trachea and about the size of a small cherry. The tumor was too low down to be removed by endotracheal operation. Dr. Elsberg, therefore, made a longtitudinal incision into the trachea, found that the tumor sprang from the fourth and fifth tracheal rings, and extirpated the growth with the knife and thoroughly cauterized the raw surface left with the actual cautery. The greater part of the tracheal wound was closed by sutures and a tracheotomy tube inserted. The patient made a very satisfactory recovery. The pathologist reported that the tumor was a fibroma. While primary tumors of the larynx were very frequent, primary growths of the trachea were rare. Theissen has recently collected 135 cases, of which 89 were benign and 46 malignant. There were only 24 cases of primary fibroma of the trachea on record, and this made 25. A second operation had to be done on this patient two months later on account of a granulation tumor—due to the tracheotomy tube—which caused some tracheal obstruction. After removal of the granulations, recovery was complete. Dr. Elsberg said that in tumors or obstruction of the larynx or trachea it was very important to have everything in readiness for tracheotomy before the anesthesia was begun, as there was often sudden collapse of the trachea walls and stoppage of breathing. In this case the patient suddenly stopped breathing soon after the anesthesia had been begun, and only the fact that the operator was ready for just such an emergency and did an immediate tracheotomy, prevented death from asphyxia.

Dr. Emil Mayer discussed this case.

Result After Krogius' Operation for Congenital Dislocation of the Patella.—Dr. Elsberg presented a patient upon whom he had performed Krogius' operation for congenital outward dislocation of the patella, with a very satisfactory result. The patient was a boy of fourteen who had an inveterate outward dislocation of the patella which interfered with his walking. When he flexed his leg at the knee it was impossible—by manual force—to prevent the patella from slipping outward almost into the popliteal space. The patient had been presented at a previous meeting of the section by Dr. Goodman. Dr. Elsberg described the various operative procedures that had been tried for this condition. The muscles of the inner aspect of the thigh had been shortened, the muscles of the outer aspect had been lengthened, attempts had been made to keep the patella in place in cases of this kind by chiseling out a depression in the anterior surface of the femur; the patella had been sewed to the periosteum of the lower end of the femur. These and other operations had been tried on these patients, but the results had not been satisfactory. Krogius of Helsingfors, a few years ago, described a method which in his own hands and in the hands of others had yielded very good results. In the case here presented the result obtained was also a very good one. The operation consisted in the raising of a fascia and muscle flap from the inner aspect of the thigh, slipping it over the patella, and sewing it into an incision made in the fascia and muscles on the outer aspect of the thigh. The rent in the fascia and muscles on the inner aspect left by the raising of the flap was then closed by sutures. By this procedure the relaxed structures on the inner side of the patella were shortened, the shortened structures on the outer side were lengthened, and the flap aided in the prevention of the outward slipping of the patella. The operation was a difficult one, requiring a prolonged dissection. Complete aseptic healing was requisite for a successful result. In the patient presented the movements at the knee were perfectly preserved; even with violent flexion the patella remained in place on the condyles of the femur.

Case of Rupture of the Spleen.—Dr. Elsberg presented a patient three years of age who had been kicked by a horse in the abdomen a few hours before he was seen. The child complained of severe pain in the right side of the abdomen. The abdomen was everywhere tender and rigid, and there were evidences of fluid free in the abdominal cavity. The most marked tenderness was in the right hypochondrium. The patient was almost in collapse. At Mt. Sinai Hospital Dr. Elsberg did a laparotomy a few hours later and found the abdomen full of fresh blood and the spleen torn transversely. The spleen was removed and all bleeding stopped by ligatures. The abdominal wall was closed with drainage. The patient's condition was very poor during and for the first twenty-four hours after the operation, but thereafter convalescence was steady and recovery complete. The child was the youngest on record—two years when the operation was performed—in whom splenectomy for traumatic rupture had been successfully performed. In answer to a question regarding the blood changes that occurred after splenectomy, Dr. Elsberg stated that the changes in the blood had been carefully watched in his case; in the beginning there was a decrease in hemoglobin, in the number of red corpuscles, and an increase in the total number of leucocytes. Within a few

weeks there was a gradual return to the normal. Those were the changes in the blood that had been observed in most patients after splenectomy.

Dr. F. Erdmann discussed these cases.

Complete Epispadias, Associated with Extrophy of the Bladder.—Dr. Carl Beck presented this case.

Case of Laryngectomy.—Dr. A. V. Moschcowitz presented a case of total extirpation of the larynx, for carcinoma. The operation was performed nineteen months ago, and thus far there was no recurrence. He wished to call attention to the fact that the entire operation, including the extirpation of the glands, was performed under local anesthesia. The patient was out of bed on the third day, and at no time was there any pulmonary involvement. He ascribed the latter in a great measure, to the use of a local anesthetic.

Dr. Emil Mayer discussed this case.

Tumors of the Larynx, with Reports of Two Laryngectomies, One Hemilaryngectomy and Three Thyrotomies.—Dr. John F. Erdmann presented this communication. In reporting these cases attention was called, not to the severity of the operation, but (1) to the anesthetic used; (2) the question of preliminary tracheotomy or not; (3) the posture and steps of the operation, and (4) the after-treatment. With regard to the anesthetic, should a preliminary tracheotomy be necessary on account of the dyspnea due to the obstruction, then cocaine or eucaine should be used and a tube introduced into the tracheotomy tube and anesthesia should be induced by vaporization or by the Junker method. In one of Dr. Erdmann's cases chloroform was a positive irritant. This condition could be overcome by spraying the mucous membrane of the trachea and larynx with a 4 per cent. or 10 per cent. solution of cocaine. Preliminary tracheotomy was not necessary in the non-obstructive cases when a complete laryngectomy was to be done; but in all thyrotomies or hemilaryngectomies it should be done as a safeguard. He did not believe in the Rose or Trendelenburg posture to overcome the dangers of an inspiration pneumonia. In complete laryngectomy the entire removal of the soft parts about the trachea and sides of the thyroid cartilage was first done, and then a blunt dissector was introduced into the cleavage between the esophagus and posterior wall of the trachea corresponding to the second and third rings. When this was accomplished the trachea was bisected and the lower end was readily pulled downward and forward by previously placed anchor sutures or volsella. Gauze was then packed into the tracheal gap and the lower end of the trachea was anchored to the skin wound in the episternal notch and the operation was then proceeded with. In the six operations recorded by him every patient was kept flat on the back with only a small sand pillow under the neck in order to give more room for exposure of the trachea, etc. The median incision was made from the episternal notch in laryngectomy to the hyoid bone. The soft parts to the isthmus of the thyroid were retracted laterally. The isthmus was bisected between two ligatures, the musculature and the thyroid cartilage were removed from the sides with blunt dissectors and scissors. Thus the cleavage be twen the oesophagus and posterior tracheal wall was carefully entered, making a clean separation at the site of the second and third rings. Then either two hooks or sutures were placed in or around the second and third rings, the trachea was bisected at the first or second or third rings and the lower portion drawn down and forward, while an assistant checked whatever oozing occurred by placing gauze in the tracheal gap. The lower end was then sutured or anchored in the lower angle of the wound, the anesthesia was continued through this portion either through a rubber tube or the tracheal tube. The next step could be done deliberately as all danger of inspiration of blood should be passed. The cricoid cartilage and the first ring of the trachea, if they were left, were seized and pulled upward and a close cleavage dissection was made between the pharyngeal and posterior laryngeal walls. Should the laryngopharyngeal structures be invaded they must be sacrificed. Excision was then done, either subepiglottic or entire. Any tears or intentional gaps in the pharynx were to be sutured. The musculature was brought together and finally the skin, with a small rubber drain, was sutured down to and behind the temporary tracheal implantation. This implantation was made permanent by suturing to the skin. In suturing the trachea to the skin care should be taken not to suture too high, as this would induce tugging of the suture and prevent complete lung expansion, thereby making an immediate operative dyspnea. In hemilaryngectomies and thyrotomies the preliminary tracheotomy gave one a great sense of comfort and allowed a careful and deliberate removal of all diseased areas. The trachea wound was packed above the site of the tube with gauze to prevent inspiration of blood. After exposure of the larynx, in doing these two operations, a fine septum saw should be introduced into the thyroid membrane and a direct median separation with the saw was readily made. The separate halves were then inspected. Should the removal of the cartilage and soft parts be decided upon, the musculature, etc., was removed, excision was begun below and upwards as in laryngectomy, and the soft parts were sutured in the median line. In case thyrotomy was necessary the soft parts invaded were removed down to the cartilage, oozing being checked by gauze or adrenalin. The thyroid halves were then sutured together by taking the soft parts in immediate contact, then a second row of sutures was inserted, and finally the skin was united. The tracheotomy tube was left in for twenty-four hours or several days, depending upon the hemorrhagic oozing and discharge. All these cases should be placed in the head-dependent posture for from twenty-four to forty-eight hours. Fluids and food should be administered by rectum for forty-eight hours at least; then water should be given by the mouth as a trial for leakage. After the fourth day, if no water leakage existed, milk might be given. Solids might be given after the union of the deper structures was assured. Constant attention by a special trained nurse, day and night, was indispensable. Constant mouth cleanliness and the same for the tube must be attended to. The patient should be allowed to sit up as soon as the secretions would allow, about twenty-four to seventy-two hours after the operation.

Drs. Mayer, Berg, and Mosely discussed this paper.

A Plea for Exploratory Incision in Suspected Depressed Fracture of the Skull.—Dr. Joseph Wilner read this paper. He said that out of 62,864 fractures collected from various statistics 1,139, or 1.8 per cent., were fractures of the skull. Sixty per cent. of fractures of the skull occurred between the ages of twenty and forty. They were nine times as frequent in men as in women. In 50 per cent. of the cases a fall was the cause, in 35 per cent. a blow, in 9 per cent. a runover accident. Fractures of the base and vault occurred with about equal frequency. Fractures of the vault occurred in the frontal bone in 44 per cent., in parietal bone 40 per cent., in the temporal bone 14 per cent., and in the occipital bone 2 per cent. of all cases. The classical signs of fractures, crepitation, and false point of motion could not be had in the majority of the cases of fracture of the skull. The cases in which these signs were present were not the most dangerous, because in such cases we were all agreed that operation was needed. But it was in the doubtful cases that the greatest danger lay. Or there might be signs and symptoms indicative of fracture during the twenty-four hours following the injury, such as unconsciousness, irregularity of the pupils, vomiting, headache, rise of temperature; and after twenty-four or forty-eight hours all these symptoms would disappear, and yet we had to deal with a depressed fracture of the vault. Unfortunately the focal nervous symptoms due to head

injury, in many cases did not develop until long after the trauma. Another unfortunate fact was that in practice no sharp line of distinction between concussion of the brain and compression of the brain could be drawn as in theory. It had been found by experience that one must not expect to get symptoms of brain compression or even of brain irritation in many of these cases. There might be a depressed fracture of sufficient severity to cause epilepsy in later years and which shortly after the injury might not show a single symptom due to depression. Errors in diagnosis might arise in the presence of a flat hematoma with hard edges. In the center of such a hematoma one might feel a depressed area, and then one must consider whether the depression existed only in the soft parts or also in the skull. Sometimes the edges of the hematoma felt like a ridge of bone, thus simulating a fracture. By a careful comparison of the two sides of the skull one could sometimes arrive at a correct diagnosis. The dangers of a depressed fracture of the skull were primary and secondary. Among the primary dangers might be mentioned injuries to the dura and brain, resulting in brain abscess or meningitis. Further the necrosis of the fracture and depressed pieces of bone might result in extradural abscess. Such an abscess might form, however, even though there were no fracture of the skull. The principal secondary dangers of a depressed fracture was epilepsy. He asked how many epileptics owed their condition to an unrecognized depressed fracture that occurred in infancy or childhood; this was hard to say. There were various ways in which changes might take place at the site of a depressed fracture which would produce cerebral irritation with resulting epilepsy. One should not lose sight of the fact that the brain was pulsating continuously, and that with each pulsation the dura impinged against the depressed portion of the bone. There was thus a constant irritation at the site of the fracture. In consequence of this irritation an osteophytic growth took place; this was a slow process, to be followed ultimately by epilepsy. Dr. Wiener believed that the dangers of an exploratory incision were generally overestimated, and the dangers of a depressed fracture underestimated. To show the dangers of operation, even in complicated cases of fractures of the vault, were very small, he said that Burkhard of Nurnberg reported out of 43 fractures without apparent complications of the contents of the skull, operative recoveries of 42 or a mortality of 2 per cent. Wagner reported 83 complicated fractures submitted to operation soon after the injury, with only two deaths, a mortality of 2.5 per cent. By operation one tried to accomplish three things, viz., (1) to transform an unfavorable relation of the fractured fragments into a favorable one, *i.e.* elevate the depressed bone and remove loose pieces; (2) to repair the injury to the dura; (3) to prevent infection.

Specimen of Multiple Fibrosarcoma of the Tongue.—Dr. Frederick Holme Wiggin presented this specimen, which he had removed from an unmarried female, aged twenty-three, of Irish descent, a domestic, who came under his care during November, 1905, complaining of an enlargement of the back of her tongue which was causing her much discomfort, as, on account of its size, it made speaking, eating, and sleeping difficult. On examination the girl appeared to be well nourished, but anemic, and rather dull mentally. She gave a negative family as well as a personal history up to about seven years previously, when she stated that she had just noticed a small growth projecting from the surface, at the back of the tongue, round at the bottom, and somewhat pointed at the top. This tumor was shown to a physician, who pulled it off, and treated the resulting sore for a time, and then, as the growth began to reappear, left it alone. The patient stated that it grew quite rapidly for a time, and then more slowly, but that of late the tumor had been enlarging quite rapidly. She also said that she had had no pain, other than that caused by the mechanical difficulty encountered in speaking, eating, and sleeping, especially the latter, as for some time past she had been obliged to sleep in a sitting posture. Examination of the patient's heart, lungs, and abdomen failed to reveal anything of an abnormal character. When, however, the mouth cavity was looked into a tumor which nearly occluded the pharynx was found, projecting from the surface of the tongue at the site of the foramen cecum, rather more prominent to the left of the median line than elsewhere, and about two and one-half inches by one inch in size. The growth was painless to the touch, but felt elastic almost to the point of fluctuation. The mucous membrane covering the growth was intact and normal in appearance. The removal of the neoplasm was advised and effected on November 24, 1905, by the speaker, by means of a longitudinal incision one and a half inches long, made through the mucous membrane and muscular tissue covering the most prominent position of the tumor to the left of the median line. The tissues were easily reflected from the tumor, which was found to be encapsulated and readily shelled out of its bed. It was about one and a half inches in diameter, and when the growth was cut into it was found to consist of soft, fatty-looking tissue. The convalescence proved uneventful, and the patient improved very much in general health and in appearance, being now able to sleep in the prone position, to swallow with comparative comfort, but her ability to speak distinctly did not improve materially. The tumor was sent for microscopical examination, to five eminent pathologists, with the result that three gave opinions favoring fibroma, and two fibrosarcoma. While the girl's health was much improved, the enlargement on the right side of the tongue previously mentioned failed to diminish in size, as it was hoped it would do. By February 1 it had perceptibly increased in size; therefore, about the 15th a second operation was undertaken, the incision this time, however, being made over the right side of the tongue. When the mucous membrane and overlying muscular tissue had been divided and dissected back for a short distance nine separate encapsulated tumors of various sizes were easily shelled out, there being but little hemorrhage, which was readily controlled by the sutures necessary to close the wound. The convalescence was uneventful. The wound healed primarily. The same differences of opinion were expressed by the pathologists, who examined the tumors removed at this operation, as in the first instance. Early in March, about three weeks after the performance of the last operation, a growth was noticed, making its appearance in the scar tissue on the right side of the tongue, which grew rapidly, measuring, when it was removed on April 12, 2 by 1 inches in size. This growth was not encapsulated as the other tumors previously removed had been, but was intimately connected with the tongue tissue, and a wide cut was made around it. When this tumor was submitted to the pathologists three were in favor of fibrosarcoma, one was in doubt, and one retained his original view as to the fibrous character of the neoplasm. April 19, one week after the third operation, a recurrence in the line of incision was discovered, which grew much more rapidly than the former one had, threatening, at the rate of progress it was making, to fill up soon the pharynx. Under trypsin injections and pancreatic extract internally, the tumor first ceased to grow and then diminished in size, until it nearly disappeared June 15. It remained quiescent till August 15. Up to September 1, when the patient was lost to observation, it seemed to have increased a little in size.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 8, 1906.

Dr. Matthias Nicoll, Jr., in the Chair.

Stricture of the Esophagus.—Dr. Matthias Nicoll, Jr., presented a boy, 11 years old. Six years ago he swallowed

a mouthful of lye. From this time he had more or less trouble with his stomach, swallowing only liquid and semi-solid food. He was first seen by Dr. Nicoll at Bellevue Clinic, when a plug of meat became lodged in his esophagus. This was removed by inverting the boy. The child presented a rather unusual sign; when swallowing a glass of water, with the phonendoscope one could hear the water as it squirted into the distended stomach. There was no doubt but that there was some strictural change in the esophagus, with more or less constant spasm. He had not been able to pass a bougie. The patient complained of no pain on swallowing.

Dr. J. Finley Bell of Englewood reported the case of a boy who swallowed some lye when two years of age. There resulted a stricture of the esophagus, with considerable dilatation above the stricture. Dr. Sands sent to Paris and obtained some special instruments with which to dilate the stricture. This was successfully done, and with permanent results. The patient was now a practising attorney-at-law in Pennsylvania.

Dr. L. E. La Fetra had seen two or three such cases at the New York Hospital, and each child was able to swallow well, only it was necessary from time to time to pass graded bougies. The webbed bougies passed readily enough and did no harm.

A Case of Atresia Ani Adnata.—Dr. Sara Welt-Kakels reported such a condition occurring in a child of three years. There was a fistula which opened into the vestibulum. The child felt no discomfort from this deformity. There was no similar malformation in the family. The fistula readily admitted a soft rubber catheter No. 9. The evacuations were normal and periodical. Where the anus should have been was a slight depression. An operation would be done, consisting of separating the gut from the vestibule and attaching it where it should be normally. The outlook for a good repair was very encouraging. Anderson's statistics had shown this condition to occur once in 15,000 children.

A Case of Hodgkin's Disease.—Dr. Henry Heiman presented a boy of 11 years. The family history was negative. There was no tuberculosis in the family. The patient was a full-term baby, breast-fed for one year. He never had malaria. The present illness began when he was two years old with a gradually increasing weakness and pallor. Swelling of the cervical glands was noticed about one and a half years ago, when intermittent fever and sweats appeared. There was no cough or expectoration. The appetite was poor and he had occasional attacks of diarrhea. There were no hemorrhages from mucous membranes and the fundus was normal. The physical condition was poor; he was about twenty pounds below the normal weight. The mucous membranes and skin were pale, and there was considerable enlargement of the lymph nodes. The cervical, axillary, and inguinal glands were the size of peas. The heart's action was rapid and irregular. There was a systolic murmur at the apex and at both basic orifices, the former being transmitted to the axilla. The abdomen was not distended and there was no ascites. The spleen was enlarged, and was felt three fingers below the free border, and was quite firm in consistency. The liver was felt three fingers below the free border. Hemoglobin was 42 per cent., red cells 3,200,000, white cells 6,600. No plasmodia were found. The differential diagnosis of white cells (160 cells) showed polymorphonuclears 78.7 per cent., large lymphocytes 13 per cent., small lymphocytes 6.9 per cent., mononuclears 0.6 per cent. The result of the blood findings justified him in making a diagnosis of Hodgkin's disease, a condition that was very rare in children under 10 years of age. It was often associated with syphilis or tuberculosis and the prognosis was generally unfavorable. The treatment was practically limited to arsenic. Many observers had reported favorable results from the use of the *x*-rays.

Dr. Louis Fischer said that the symptoms presented might be caused by some latent lesion in the lungs. Pulmonary conditions should be carefully excluded before making a diagnosis of Hodgkin's disease. In one of his cases there was a marked leucocytosis and a reduction in the hemoglobin percentage and a diagnosis of Hodgkin's disease was made by two good men. Three months later the child developed a cough, and there was a breaking down in the lungs, followed by a retropharyngeal abscess, caries of the cervical vertebræ, and the symptoms of tuberculosis.

Dr. L. E. La Fetra asked if tuberculin had been used. He referred to a case seen by him in which Dr. Jacobi had ordered the use of arsenic in large doses and with wonderful results. The child had a swelling almost the size of a large grape fruit; this came down under the use of Fowler's solution, the dose being increased to 100 minims a day.

Dr. Henry Heiman said that it had been impossible to administer tuberculin because of the constant temperature, which varied from 101° to 103°.

Whooping Cough and Its Treatment by an Improved Abdominal Belt.—Dr. Theron W. Kilmer said that since writing his first paper three years ago upon the treatment of pertussis by means of a slightly constricting elastic abdominal belt, about 95 per cent. of the cases had been positively benefited, and this was especially true with regard to the cessation of the vomiting. The first belt was composed of a long strip of silk elastic webbing placed over a stockinette band. The new belt was made of linen with a strip of elastic webbing of silk two inches wide, inserted on either side. This gave the belt elasticity, yet did not add materially to its weight. It laced in the back, and was worn over the undershirt or band. The width for infants should be about four to five inches, and for older children from five to eight inches. The length of the belt should be such that when complete it should measure three inches less than the circumference of the abdomen at the navel. The degree of constriction should be determined in each individual case; usually a slight degree of constriction was sufficient to produce a moderation of the cough and a complete cessation of the vomiting. If after applying the belt the symptoms do not abate, tighten it slightly. In dispensary cases and where parents could not afford the belt, he used ordinary muslin binder with satisfactory results.

Dr. Matthias Nicoll, Jr., had been favorably impressed with the belt; it seemed to lessen the severity of the paroxysms and diminished the vomiting.

Dr. Louis Curtis Ager said that a modification of the belt had been used at the clinic on Long Island with marked cessation of the vomiting in some cases. He thought the effect of the belt might to a certain extent be mental. One or two children with defective mentality were made worse, the vomiting increasing rather than diminishing. In one case the belt had to be removed because of the severity of the paroxysms.

Dr. Hoag said he had used the belt in a large number of cases of whooping cough, and those who were not conversant with its usefulness could not comprehend the advantages to be derived from it. The number of paroxysms were unquestionably and materially diminished, and in a large number of cases the vomiting decreased from 50 per cent. to 75 per cent., and occasionally it ceased entirely.

Dr. Elisha Mather Sill made a report on 161 cases of whooping cough seen during the past year. There were twenty cases under the age of one year; thirty-five cases between the ages of one and two years; ninety-five cases between the ages of two and six years; and the remainder were over six years of age. Seventeen of the twenty cases under one year had complications. Of the thirty-five cases between the ages of one and two years fifteen had complications. Of the remaining cases twenty-seven had complications. When the belt was applied during the catarrhal

stage the patients were very much benefited; the paroxysms were reduced in number as well as their severity. The disease occurred most frequently during the months of March, May, September, and October. Usually the vomiting ceased a very short time after the application of the belt. Fresh air was insisted upon in the treatment. Out of the 161 cases there were fifty-nine complications. The old-fashioned binder was used in most instances.

Notes from the Diary of a Case of Splenomegaly.—Dr. Eli Long presented a child born after a perfectly normal labor. When fifteen months old he had a severe attack of diarrhea lasting ten days. Emaciation was extreme. The abdomen was enlarged and the spleen was palpable. He then had malaria fever, low in the morning, high in the afternoon, lasting four weeks. The liver was enlarged with the spleen. When he was three and a half years old the use of the Roentgen rays was advised, and these were given three times a week for nine months. The bowels were irrigated with saline solution twice a day with an improvement in the colitis from which he suffered. When five years old the child had jaundice and epistaxis, and six months later cyanosis appeared, especially marked on exercise. When fifteen months old the malaria plasmodia were noted. When two years old the hemoglobin was 62 per cent., the red cells 3,912,000, and the white cells 4,000. When three and a half years old no plasmodia were found and no indican. When five and a half years old there was slight reduction in the hemoglobin, as well as in the number and size of the red cells. The urine and stools were normal. The circumference at the nipple line was 20½ inches; at the ribs, 23¼ inches; at the umbilicus, 28 inches. The height was 3 feet 2½ inches; the weight was 31¼ pounds. When the child was seen by Dr. Long he was poorly nourished, and had a slight cyanosis. A dry scalp was noted, and there was an eczema behind the ears. There were no evidences of adenoids. The cervical glands were slightly enlarged. The axillary glands were not palpable, but the epitrochlear glands were, especially on the right side. The inguinal glands were slightly enlarged. The lungs were normal. The apex of the heart was displaced upwards and to the left about one-fourth of an inch outside the nipple line and one-eighth inch below. The ensiform appeared to be displaced to the right. The abdomen was very prominent. The liver was enlarged and felt soft. The spleen was hard. With regard to the cause, malaria was ruled out because on only one occasion was the plasmodium found. There was no leucocytosis, therefore no leukemia. The duration of the disease was too long to admit of its being sarcoma. Congenital syphilis gave signs referable to the teeth and bones. He did not believe the child had rachitis. The case was, in all probability, one of splenomegaly, the bone lesions being possibly due to rickets. He believed that the malaria was the cause of the hypertrophy of the spleen and liver, with the possibility of an intestinal intoxication as a factor.

The Principle of the Top Milk.—Dr. Henry Dwight Chapin read this paper. He believed that the top milk method, when its advantages became thoroughly and generally known and appreciated, would undoubtedly displace all other methods. The strong point of this method was the ease with which percentages could be varied and the mixtures made by nurse or mother. The principles on which the percentage modification by the top milk method were based were very simple, and were as follows: The fat of the milk being lighter than the serum rises to the top as cream. The proteids and sugar remained distributed throughout the milk, but were slightly less in the rich cream of the upper layers. There were from five to seven ounces of cream to a quart of milk. If this cream was all removed along with enough milk to make sixteen ounces, there would be two pints of milk, one containing all the fat of a quart of milk, and the other pint being practically fat free. It was self-evident that the percentage of fat in the pint containing all the fat of a quart or two pints of milk would be twice that of the original quart. If this was 4 per cent. there would be 8 per cent. in the top milk. If all the fat was in the one-third of a quart of milk the percentage would be three times 4 per cent. or 12 per cent. In practice all of the fat would not rise in the cream, so this mathematical ratio did not hold exactly good. Milk did not run absolutely constant in fat percentage, so a margin of error must be allowed for. But by working on a 4 per cent. basis the error would always be only a little above or below the calculated percentage. The principles involved in the use of the top milk were (1) the use of milk bottled at the dairy as soon as possible after milking; (2) the rapid cooling of the bottled milk, which retarded bacterial growth; (3) the taking of definite quantities from the upper portion of the quart of milk which should include *all* of the cream. After these steps had been followed, preparation of the food consisted in simply diluting and adding sugar.

Dr. Thomas S. Southworth said that he believed it to be a safe postulate to say that the man with the greatest experience used with the greatest success some flexible method of infant feeding; this would apply to two methods, the milk and cream mixtures, and the top milk mixtures. The latter had a distinct advantage in that they gave gravity and not centrifugal cream. Gravity cream was less manipulated than the centrifugal. The method of using top milk was applicable to city as well as to country. There were variations in the top milk method, but they were not so great.

Dr. Godfrey Roger Pisek favored the use of the glass modifier, which had been used by him with the most gratifying results.

Dr. L. E. La Fetra said that top milk feeding had many advantages in infant feeding; it was a safe method and very simple in application. This method prevailed at the Vanderbilt Clinic and with very gratifying results. Mothers were made to understand the method and carried it out with perfect satisfaction.

Dr. Elias H. Bartley said that there were but two grades of cream to be had in Brooklyn, the 20 per cent. and the 40 per cent. A difficulty to be met was the fact that one could not rely upon the same composition of the milk, even from the same dairy. The percentage might remain the same, so far as the proteids were concerned, but not so regarding the fats. Unless they had a standardized milk they could claim no accuracy.

Dr. Chapin said that he claimed for the top milk method a constant relationship between the fats and the proteids. What he offered he considered to be practical. In New York City the fat percentage was a little over 4 per cent, and this was a commercial matter, because, if the fat percentage was higher, the dealers could not afford to sell it at the price they now obtained.

Chicago Medical Society.

At a meeting held October 24, 1906, there was a symposium on "Renal Calculi." Dr. Charles L. Mix discussed the etiology and symptomatology. He said that renal calculus was not found commonly in children or in the very old. It was found between the extremes of life. While Senator maintained that renal calculi occurred largely in the poor, many surgeons believed they were more common in the well-to-do or middle classes. Heredity had some bearing. It was held by some writers that a sedentary occupation predisposed to stones. The author thought it had nothing to do with it. Renal calculi were more common in some parts of the globe than in others. For instance, they were common in India, quite common in Asia, and common in Egypt. In America, however, very little could be said with reference to the geographical distribution of renal calculi, as they were as prevalent in one part of the country

as another. Renal calculi were the products of bacterial action and infection. Neoplasms of the kidney were capable of giving rise to stones without the mediation of bacterial action. In all bacteriemic diseases it was possible for the bacteria to make their way into the kidneys and exert an unfavorable influence upon the mucous membrane of the pelvis of the kidney, giving rise to a slight amount of catarrhal exudate, which might in turn serve as the nucleus of a stone. Tuberculosis of the kidney and stone of the kidney were not infrequently concomitant affairs. He described at considerable length the symptoms of renal calculus. Dr. ALFRED C. CROFTAN discussed the medical treatment of renal calculi. Dr. MAX REICHMANN pointed out the value and importance of the *x*-ray in the diagnosis of renal calculus. Dr. ARTHUR DEAN BEVAN divided the cases for surgical treatment into three groups. First, the cases in which surgical treatment was imperative; second, those in which it was desirable, but not imperative, and, third, those in which it was not desirable. In the first group he included cases of calculous anuria. These cases were very rare. They presented themselves under two general types, the purely obstructive, and the reflex anuria types. In the purely obstructive type there was obstruction of the kidney by calculous disease, or obstruction of the ureter of long-standing on one side. Following that, the other kidney became involved, with obstruction of the remaining ureter. He had had the opportunity to study three such cases. In these no urine was excreted for a period of days. Individuals with obstructive anuria had lived as long as twenty-one days without excreting a single drop of urine. The second type of calculous anuria was reflex anuria. The clinical picture was something like this: An individual had one healthy kidney, with the ureter of the other kidney obstructed by a calculus, and as a consequence there was great intrarenal tension. The obstructed kidney did not excrete any urine. The opposite kidney might not excrete any urine, except possibly by reflex action, on account of the enormous intrarenal tension of the affected side. In calculous anuria surgical treatment was imperative, although the surgeon should wait in these cases, if possible, forty-eight hours before operating, hoping that the calculus would be passed. In the third group of imperative operations was the condition where there was an obstruction of the ureter on one side, not anuria, because the other kidney was secreting, but where from the evidence one was led to believe that there was obstruction of the ureter upon one side, and where it was further possible that if this obstruction continued the integrity of the kidney might be menaced. Here the question of time element was important. In these cases he had waited a week or longer before operating, and had been rewarded by the passage of the stone in some, and had found that even the weight of the stone had not destroyed the secreting tissue of the kidney. The subject was further discussed by Drs. JAMES B. HERRICK, ARTHUR R. ELLIOTT, VICTOR J. BACCUS, and CARL WAGNER.

Action of Roentgen Rays on Cultures of Achorion and Trichophyton.—Angelantonio Mancini has treated twelve children with Roentgen rays who were affected with *Trichophyton tonsurans* and favus, and has made cultures of the parasite in the most favorable media, and subjected these cultures to the *x*-rays, with a view to ascertain what effect the rays have on the parasite itself. He finds that the *x*-rays do not destroy or affect *Achorion schonleinii* or *Trichophyton tonsurans* when cultivated in agar, lactose, or malted agar. The macroscopic and microscopic appearances are not changed. Hence, we must believe that the rays cannot have any effect on the parasite when resident in the skin. The author believes that the depilation due to the rays has an important effect on the destruction of the parasite in the scalp. At the same time the tissues are so modified as to render them more resistant to the parasites. If the rays are applied too strong a permanent baldness is produced, but, when properly applied, the cure is easy and complete.—*Giornale Medico del Regio Esercito.*

Therapeutic Hints.

Bronchopneumonia in Children.—William A. Wood recommends in cases of bronchitis with much prostration:

℞ Spt. ammon. aromat.....3i
Syr. senegæ.....3i
Tinct. scillæ.....3ss
Syr. prun. virg.....3ii

M. S. One half to one teaspoonful every two hours. In children of eight years and upward the muriate of ammonia in small doses may be substituted for the aromatic spirit of ammonia. In case the inflammation has extended to the lung substance and bronchopneumonia is developed, the chest should be enveloped in a jacket poultice of linseed meal covered with oiled silk; and if there is high fever give as follows:

℞ Potassi citratis.....3j
Spt. ammon. arom.....gtt. xv
Spt. ether nit.....3ss
Liq. ammon. acet.....3iij
Glycerin.....3ss

M. S. One-half to one teaspoonful every two hours.
—*Wisconsin Medical Recorder.*

Acute Rheumatism.—The following are recommended by Burney Yeo:

℞ Sodii bicarb.....gr. v
Ammon. bicarb.....gr. v
Acid. salicyl.....gr. xx
Aquæ ad.....3i

M. S. Take at a dose.

℞ Salicini.....3ii
Pot. bicarb.
Sodii bicarb.....āā 3iss
M. et div. in pulv. vi.

S. One powder every three or four hours dissolved in a wineglassful of hot milk and water.

Toothache.—For pain due to pericementitis, J. P. Buckley uses:

℞ Tinct. aconiti.....3i
Chloroformi.....3iv
Menthol.....gr. xx

M. Sig.: Paint over gums.
—*Dental Review.*

Corns.—

℞ Ac. salicyl.....3iiss
Ext. cannab. ind.....gr. xv
Ac. acet. glacial.....3ss
Ol. terebinth.....3i
Cocain.....3ss
Collod. flex.....3iiiss

M. S. Apply at night.
—E. S. McKEE in *Southern Practitioner.*

Alopecia.—Sabouraud recommends the following:

℞ Ol. cadini.....3iiss
Lanolin.....3v
Acid pyrogallici
Hydrarg. oxidi flavi
Resorcin.....āā gr. xv
M. et ft. unguentum.

℞ Lanolin.
Petrolati
Ol. cadini.....āā 3iiss
Ol. betulæ.....mxv
Hydrarg. subsulph. flav.
Sulph. precipitat.....āā gr. xv
M. et ft. unguentum.

Lumbago.—

℞ Sodii salicylat.....3ss
Potassii iodidi.....3ii
Syr. sarsaparillæ comp.....3iss
Aquæ q.s.....3ii

M. S. A teaspoonful in water after meals.
—S. SOLIS COHEN.

Frost-bite.—

℞ Icthyol.
Resorcin.
Acid. tannic.....āā 3i
Aquæ.....3v

M. S. Apply locally once or twice daily.
—BOECK.

Blepharitis.—

℞ Resorcin.....0.2
Hydrarg. præcip. alb.....0.25
Lanolin.....20.0
M. ft. unguentum.

S. Apply to the eyelids at bedtime.
—KANTOROWICZ.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.*

ARKANSAS STATE BOARD OF MEDICAL EXAMINERS.

July 10, 1906.

ANATOMY.

1. At what time in the development of the fetus is the hair formed?
2. Give the general classification of bones.
3. Name the bones of the upper extremity.
4. Describe the diaphragm, giving origin, insertion, nerve supply, and action.
5. Name the superficial group of the muscles of the abdomen.
6. Name the openings of the heart.
7. Name the branches of the anterior tibial artery.
8. Describe the pia-mater.
9. Describe the uterus.
10. Describe the gall-bladder.

PHYSIOLOGY.

1. Name and describe the glands of the intestines and tell in which portion of the intestine each kind is situated.
2. Describe the glycogenic function of the liver and tell the destination of glycogen.
3. Give origin, distribution, and function of the fifth pair of cranial nerves.
4. (a) How is the nervous system arranged anatomically? (b) Give a short sketch of each system.
5. How many pairs of spinal nerves are there? Describe them.

CHEMISTRY.

1. What is albumin?
2. In what form in nature do we find albumin in its purest form?
3. In what case of poisoning do we use albumin as an antidote?
4. Name a metallic poison for which albumin is especially recommended.
5. What is meant by toxicology?
6. What causes the decay of animal or vegetable matter when deprived of life?
7. What is meant by ptomain poison?
8. What is the origin of ptomain poison, or, in other words, how and from what are ptomains derived?
9. When the atmosphere we live in becomes charged with an excess of carbonic acid, how is it purified and made fit for the support of animal life?

MATERIA MEDICA AND THERAPEUTICS.

1. What is an alkaloid, a tincture, a fluid extract?
2. Name four different classes of medicine, with an example of each class. Give dose of example.
3. What drugs would you use hypodermatically to meet the following requirements? (a) To stimulate the heart's action; (b) to produce emesis; (c) to control hemorrhage.
4. What is the strength of normal salt solution? Give indications for its use and mode of administration.
5. Give principal alkaloid of belladonna and indications for its use; also dose.
6. Name the three (3) most used preparations of opium, and how much of each contains one grain of opium.
7. Give hypodermatic dose of the following: Sulphate of strychnine, sulphate of atropine, sulphate of morphine, apomorphine hydrochlorate, nitroglycerin, and pilocarpine hydrochlorate.
8. Write a complete prescription for a diuretic containing not less than three ingredients.
9. How are the cathartic effects produced by salines?
10. How is nitrite of amyl used, and for what purpose?

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the student with the general character of these examinations and to inspire him with confidence in the result of his trial.

PRACTICE.

1. Differentiate between acute alcoholism and apoplexy.
2. Give etiology, physical signs, and treatment of pericarditis.
3. Give physical signs of acute lobar pneumonia.
4. Give etiology, diagnosis, and treatment of biliary colic.
5. What are the two common complications of typhoid fever during the second or third week? and give treatment.
6. Describe a case of acute catarrhal dysentery and give treatment.
7. Give etiology, diagnosis, and treatment of gonorrhea.
8. Give diagnosis and treatment of acute articular rheumatism.
9. Give etiology, morbid anatomy, period of measles incubation, common complications and their treatment.
10. Describe three stages of malarial paroxysm and give treatment in each stage.

SURGERY.

1. Describe symptoms and operation for gallstones.
2. Through what would you pass, in the open method of operating for hydrocele?
3. What are the contraindications for hemorrhoidal operation?
4. How would you differentiate between gallstones, gastric ulcer, and appendicitis?
5. Give surgical treatment for Bright's disease.

OBSTETRICS.

1. Describe the fallopian tubes.
2. Describe the placenta and give its functions.
3. Give differential diagnosis of pregnancy from ovarian cystoma.
4. Give treatment for threatened abortion.
5. Write prescription for vaginitis.
6. Give treatment for placenta previa.
7. What are the indications for vaginal tamponing?
8. Give method of performing cephalic version.
9. Give treatment of uterine inertia.
10. Give management of normal labor.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ARKANSAS STATE BOARD OF MEDICAL EXAMINERS.

July 10, 1906.

ANATOMY.

1. Hair begins to develop at about the third month of fetal life.

PHYSIOLOGY.

1. Lieberkühn's glands are found throughout the small and large intestine: Brunner's glands are found in the duodenum: the solitary glands are found throughout the entire intestine, but are most abundant in the lower part of the ileum and the upper part of the large intestine; Peyer's patches are found in the lower two-thirds of the small intestine, chiefly in the ileum.
2. The destination of glycogen: It is converted into sugar (dextrose), is given off to the blood, and is finally oxidized in the tissues.

CHEMISTRY.

1. Albumin is a protein substance, found in most animal tissues, and consisting of carbon, hydrogen, oxygen, nitrogen, and sulphur. It is soluble in pure water, and is coagulated by heat.
2. In the white of hen's egg.
3. and 4. In mercurial poisoning (by corrosive sublimate), also in poisoning by nitrate of silver.
5. By toxicology is meant that branch of medical science which appertains to poisons: it includes their character, origin, actions, symptoms produced, antidotes, treatment, and detection.
6. The process of slow oxidation.
7. By ptomain poison is meant the poisonous products of putrefaction of dead animal tissues and fluids.
8. Ptomains are derived from dead animal matter.
9. By the action of plants: the chlorophyl of which, under the influence of sunlight, decomposes the CO_2 into C and O_2. The plants retain the carbon in organic combination, and return the oxygen to the air.

MATERIA MEDICA AND THERAPEUTICS.

1. An *alkaloid* is an organic, nitrogenized substance, alkaline in reaction, and capable of combining with acids

to form salts in the same way that ammonia does. A *tincture* is an alcoholic solution of a nonvolatile substance. A *fluid extract* is a permanent solution of a vegetable drug, in which one cubic centimeter of the solution represents one gram of the drug.

2. (1) Emetics, as tartar emetic, dose one to two grains; (2) diuretics, as potassium acetate, dose five to sixty grains; (3) hypnotics, as chloral hydrate, dose five to twenty grains; (4) mydriatics, as atropine sulphate, dose one one-hundred-and-twentieth to one-twentieth of a grain.

3. To stimulate the heart's action, strychnine: to produce emesis, apomorphine: to control hemorrhage, ergot.

6. Pulvis ipecacuanhæ et opii, ten grains; tinctura opii, about ten mimims; tinctura opii camphorata, about half an ounce.

8. ℞ Potassii acetatis
Potassii bitartratis
Potassii citratis..... .....āā ʒij
Aquæ destillatæ q.s.....ad ʒviij. Misce

Signa: One tablespoonful three times a day, in half a glass of water.

9. Salines cause a great increase in the amount of fluid secreted by the intestinal glands; they also hinder the reabsorption of this fluid. The result is an accumulation of fluid in the intestine, which, by distention, excites peristalsis.

SURGERY.

2. Skin, dartos, intercolumnar fascia, cremasteric fascia, infundibuliform fascia, and the parietal layer of the tunica vaginalis.

OBSTETRICS.

7. For controlling hemorrhage, either vaginal or uterine; to exert pressure; to support the uterus; as a means of applying medication locally; and for depleting inflammatory conditions.

Nebraska State Board of Health.*

May 29-31, 1906.

PHYSIOLOGY.

1. In the *embryo*, the red blood corpuscles are derived from cells in the vascular area of the mesoblast; in the *adult*, they are derived chiefly from the red marrow of bones, also from the spleen. As to their fate, they are probably broken up in the liver and spleen. In form they are circular biconcave discs. Their size is about 1-3200 of an inch in diameter. In number they are about 5,000,000 to the cubic millimeter in males, and about 4,500,000 in females. Their function is to carry oxygen from the lungs to the tissues of the body; this is accomplished by the hemoglobin, which has a great affinity for oxygen.

2. By endocardiac pressure is meant the pressure of the blood within the heart. Pressure in the arteries and capillaries is caused by the contractions of the heart, by peripheral resistance, and by the elasticity of the vessel walls. In the veins pressure is caused by the elasticity of the vessel walls, by cardiac contraction, also by contraction of the skeletal muscles in general and particularly of the muscles of inspiration, and by the continuous traction of the lungs.

3. The mechanism of the secretion is twofold. (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea and principal solids are eliminated.

8. Ameboid movement is a property common to all blood leucocytes. Some of the physiological uses of the leucocytes are: (1) They serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine; (4) they help to maintain the proper proteid content of the blood plasma.

9. It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.

*The questions were published in the issue of November 3.

10. The difference between the corpus luteum of pregnancy and that of menstruation is best shown in the following table from Dalton, which was reprinted in nearly all the text-books of ten or twenty years ago:

	Corpus Luteum of Menstruation	*Corpus Luteum of Pregnancy*
At the end of three weeks.	Three-quarters of an inch in diameter; central clot reddish; convoluted wall pale.	
One month...	Smaller; convoluted wall bright yellow; clot still reddish.	Larger; convoluted wall bright yellow; clot still reddish.
Two months..	Reduced to the condition of an insignificant cicatrix.	Seven-eighths of an inch in diameter; convoluted wall bright yellow; clot perfectly decolorized.
Six months...	Absent.	Still as large as at end of second month; clot fibrinous; convoluted wall paler
Nine months.	Absent.	One-half an inch in diameter; central clot converted into a radiating cicatrix; the external wall tolerably thick and convoluted, but without any bright yellow color.

CHEMISTRY.

1. Organic chemistry is the chemistry of the compounds of carbon. An atom is the smallest part of an element that can take part in a chemical reaction. An element is a substance which cannot, by any known means, be split up into dissimilar substances.

2. By diluting the cow's milk and adding lactose it can be made to approximate human milk.

3. To make hydrogen: $Zn+H_2SO_4=ZnSO_4+H_2$.
To make laughing gas: $(NH_4)NO_3+Heat=2H_2O+N_2O$.

4. Chemical tests for strychnine. With concentrated H_2SO_4 it forms a colorless solution; a crystal of potassium bichromate, if drawn through this solution, produces a track of color, which is in turn blue, violet, rose-colored, and yellow. For arsenic. Marsh's and Reinsch's are the two most commonly used tests. Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry, glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

5. Both fermentation and putrefaction are forms of decomposition of organic matter under certain favorable conditions. When the organic matter is composed of carbon, hydrogen, and oxygen only, the process is called fermentation; when nitrogen and sulphur are also present, putrefaction is said to occur.

6. Heller's test for albumin is performed as follows: Pour into a clean test-tube a layer of HNO_3 about half an inch deep; then with a pipette carefully float on to the surface of this acid a layer of urine, taking care that the liquids do not mix. If albumin is present a cloudy ring, with sharply defined borders, will appear at the point of junction of the two layers.

8. The average amount of solids in the urine is about 850 to 950 grains in twenty-four hours. It can be estimated as follows: Take the specific gravity of the twenty-four hours' output; multiply the two last figures of this specific gravity by the number of ounces of urine passed in the twenty-four hours; multiply this product by 1.1; this represents the total urinary solids in grains.

9. The common determinations in chemical examinations of the gastric juice are for total acidity, for free HCl, for combined HCl, for total HCl, for acid salts, for lactic and organic acids.

10. Proteids consist of carbon, hydrogen, oxygen, nitrogen, and sulphur, some also contain phosphorus, and a few iron.

SURGERY.

2. In *empyema* we find limited motion on the affected side, edema and redness in the intercostal spaces, dulness on percussion, absence of breath sounds, diminished fremitus and resonance, chills, sweats, high fever, dyspnea, and expectoration of offensive sputum; exploratory puncture brings pus, and there is a high leucocytosis. In *hemothorax* there may be dullness on percussion, possible absence of breath sounds, diminished vocal fremitus, and if the quantity of blood is large there will be the usual symptoms of hemorrhage, shock, thirst, pallor, small thready pulse, and dyspnea. In *bronchiectasis* there are large quantities of sputum brought up at intervals; it is sour or offensive, and on standing separates into two layers.

4. *Intussusception:* tenesmus, pain of sudden onset and

continuous, diarrhea, normal or subnormal temperature, weak pulse, stercoraceous vomiting, and the intestine may protrude at the rectum. *Floating kidney*: kidney may be felt, generally on right side, heavy dragging pain in abdomen, which is better on lying down, mental anxiety and sometimes hysterical symptoms, and general relief is afforded by supporting the abdominal walls. *Stricture of pylorus*: the symptoms are those of dilated stomach; the stomach gets full and distintended, and is relieved by very copious vomiting at long intervals. *Bubonocele*: tumor in the inguinal canal, with symptoms of hernia, can be reduced, and gives impulse on coughing. *Varicocele*: feels like a bag of worms, does not transmit light, is dull on percussion, elastic, soft, and gives an impulse on coughing. *Undescended testicle*: scrotum on the affected side is empty, testis is in inguinal canal or in iliac fossa just above Poupart's ligament, on pressure there is pain and the peculiar "testicular sensation."

7. The etiology of carcinoma of the breast is not definitely known. Among the theories offered are: Cohnheim's, of embryonic remains; injury or irritation, parasites or bacteria, and inherited tendencies have all been supposed to be causes, either predisposing or exciting. Further the breast is particularly liable to changes in functional activity, which may tend to formation of cancerous growth. It also follows Paget's disease (eczema) of the nipple.

9. Pain in the abdominal region, if *diffuse* may denote peritonitis or hysteria; if *localized* it may indicate various diseases or injuries, *e.g.* in the right iliac region, it denotes appendicitis; *acute* pain generally implies acute inflammation, or perforation or occlusion of a duct; *paroxysmal* pain generally means colic, either intestinal, hepatic, renal, vesical or uterine; *persistent* pain is often found in diseases of the abdominal viscera, aneurysms, and diseases of the vertebræ.

OBSTETRICS AND GYNECOLOGY.

4. *Ovarian cyst*: absence of the chief signs of pregnancy; there may be the characteristic facies; the tumor is soft, fluctuating, is more to one side, and does not show fetal signs. *Ascites*: absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient, on lying down there is bulging at the sides; the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient. *Pregnancy*: the tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health, may also help in arriving at a diagnosis.

7. *Symptoms* of death of child *in utero*, are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited. *Treatment*: Abortion or premature labor must be induced, and the contents of the uterus removed immediately.

PATHOLOGY.

1. Pathology is that branch of science which treats of disease; it includes the causes, nature, manifestations, structural changes, and results.

3. Phagocytosis is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria.

9. *Gastritis*: is generally caused by indiscretions in diet, or by mental worry, it may occur at any time of life, and is characterized by pain in the epigastric region which generally comes on after eating; there is apt to be morning vomiting, the vomitus consisting of fluid with undigested particles of food; there is seldom hemorrhage; the stomach may be enlarged, and examination of the gastric contents shows free HCl diminished or absent. *Ulcer of stomach*: is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five, after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl. *Cancer of stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and occur between the ages of twenty and forty-five; after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

PRACTICE.

5. Hematuria may be due to (1) conditions in which the blood is affected, as in the infectious diseases, in scurvy, pernicious anemia, and purpura; (2) to traumatisms or inflammations in any part of the urinary tract; (3) to congestion of the kidneys secondary to disease of the lungs, heart, or liver. In *renal* hematuria the blood and urine are intimately mixed, tube casts are apt to be present, and there may be renal colic or pain in the lumbar region. In *vesical* hematuria the blood and urine are not so well mixed, and pure blood is apt to be passed at the end of urination.

9. The knee jerk is nearly always present in health, and denotes a healthy condition of the entire reflex arc (tendon, afferent, or sensory nerve, posterior roots and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself). It is absent when there is a lesion which affects any part of this reflex arc; such is the case in locomotor ataxia, poliomyelitis, Landry's paralysis, neuritis, in apoplexy just after the shock, and in epilepsy following the convulsion, etc. It is exaggerated in increased irritability of the spinal cord, in organic diseases of the cerebrum, and in some incomplete lesions of the cord.

MATERIA MEDICA AND THERAPEUTICS.

6. The non-medicinal treatment of cardiac insufficiency consists in rest, as complete as possible; light, nutritious, and easily assimilable food; avoidance of all forms of excitement, and overexercise, also abstinence from alcohol and tobacco; good general hygienic conditions and avoidance of exposure and cold. Massage, medicated baths, and various forms of muscular movements have also been recommended.

Regular Board Medical Examiners, State of Georgia.*

April 3 and 4, 1906.

CHEMISTRY.

1. (1) Calomel, Hg_2Cl_2, dose one twentieth of a grain to ten grains.
(2) Chloral hydrate, CCl_3CHO+H_2O, dose twenty grains.
(3) Potassium chlorate, $KClO_3$, dose five to twenty grains.
(4) Amyl nitrite, $C_5H_{11}NO_2$, dose two to five minims (to be inhaled).
(5) Bismuth subnitrate, $BiONO_3$, dose five to thirty grains.

2. Epsom salt is magnesium sulphate, $MgSO_4$;
Glauber's salt is sodium sulphate, Na_2SO_4;
Rochelle salt is potassium sodium tartrate, $KNaC_4H_4O_6$.

3. Potassium cyanide, tartar emetic, arsenic, trioxide, potassium nitrate (saltpeter), and corrosive sublimate. The antidote for corrosive sublimate is the white of egg, or milk, followed by an emetic.

4. The nonmetallic elements found, in various combinations, in the tissues of the body are hydrogen, oxygen, fluorine, chlorine, iodine, sulphur, nitrogen, phosphorus, carbon, and silicon.

5. *Urates* are found in acid urine, have a pinkish color, dissolve on being warmed, and, microscopically, are generally amorphous, but may be crystalline. *Phosphates* occur in alkaline urine, and do not dissolve on being heated.

MATERIA MEDICA AND THERAPEUTICS.

4. Hemostatics are agents which, on being administered internally, arrest hemorrhage. Agents which act in this manner on being applied locally are called styptics. The former act by causing the vessels to contract; the latter sometimes in the same way and sometimes by promoting clot formation in the mouths of the wounded and bleeding vessels. Ergot, gallic acid, digitalis, hamamelis, and ipecac are hemostatics. As styptics may be named the actual cautery, acids, nitrate of silver, alum, collodion, and vegetable astringents.

5. ℞ Liquoris potassii arsenitis..... ♏xxx
Tincturæ nucis vomicæ..... ʒiss
Aquæ destillatæ q.s. ad..... ʒiii
Misce, et signa. Shake the bottle. Take one teaspoonful in water, three times a day, after meals.

OBSTETRICS AND DISEASES OF CHILDREN.

2. *Pregnancy*: the tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other

*The questions were published in the issue of November 17.

signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Ovarian cystoma: absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

Ascites: absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides; the tumor fluctuates, and percussion shows dulness in the flanks, with resonance in the median line, but the dulness varies with the position of the patient.

Uterine fibroid: menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

3. Braxton Hick's sign of pregnancy is the rhythmical contraction of the walls of the uterus, lasting for from thirty to sixty seconds, and occurring at irregular intervals, of from five to about twenty minutes. It is always found in pregnancy, whether the fetus is alive or dead, but it is also found in some other conditions. It may be obtained by simply grasping the uterus through the abdominal wall; this should be done gently, and without making pressure.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	January	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	January	8

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending November 24, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	307	158
Diphtheria	298	43
Measles	112	5
Scarlet Fever	119	7
Smallpox	2	—
Varicella	79	—
Typhoid Fever	115	20
Whooping Cough	86	4
Cerebrospinal Meningitis	9	14
Malarial Fever		
Totals	1127	251

Modifications of the Structure of the Mammary Gland Due to Suspension of Lactation.—E. Meynier has made experimental studies of the mammary glands of animals when nursing had been stopped suddenly at various periods of lactation, and gives us his conclusions as to its effect on the gland. The phenomena resulting from interruption of lactation differ in different animals and in different parts of the same gland. There are three stages in the changes that take place. In the first stage there is a tendency to resume the function and a stagnation of large quantities of milk in the gland. In the second stage the milk assumes the appearance of colostrum. In the third, atrophy goes on. At first leucocytes are infrequent and mononucleated; later the polynucleated cells predominate, and in the end small mononucleated cells are most abundant. The epithelial cells contain small fat globules. The interlobular and interstitial connective tissue increases gradually, but the glandular acini are not compressed.—*Rivista Critica di Clinica Pediatrica.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending November 23, 1906:

TRYPSIN FOR THE CURE OF CANCER.

WITH REPORT OF THE MICROSCOPIC EXAMINATION OF A CANCEROUS TUMOR OF THE BREAST THUS TREATED.

By WILLIAM J. MORTON, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, AND ELECTROTHERAPEUTICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Much interest on the part of the medical world seems to be attached to the use of trypsin for the cure of cancer as proposed by Dr. John Beard, University Lecturer in Comparative Embryology of the University of Edinburgh.

Attracted by the logical doctrine presented by Dr. Beard, the writer as early as April last instituted a series of experiments with a view to testing this new theory. These experiments consist of the consecutive use of trypsin in a series of about thirty cases, hospital and private. They arose in connection with a series of cases I had under treatment by other measures, mainly *x*-ray, radium, and fluorescence.

Without permitting myself to express a definite opinion, which at this moment I think would be premature, it nevertheless seems to me that an amount of experience has by this time been accumulated which may be of value to others. A salient fact may be stated at the outset, and that is that the cancerous tumor itself exhibits very frequently a definite reaction to the trypsin treatment. In some instances this reaction is accompanied by great amelioration of the disease. It may also here be pointed out that a general and constitutional reaction frequently ensues. Most of the cases here presented were far advanced and practically hopeless, as well as inoperable. For this reason, benefit derived has greater weight, and would lead to the conclusion that if such cases could have been treated earlier, the results would have been more favorable. Two cases of quite extensive face cancer are cured to date, Cases 10 and 14. In Case 1 a most remarkable atrophy of an entire cancerous breast ensued. In many the progress of the disease has come to a standstill. Accepting the evidence of microscopical examination in Case 1, it is safe to assume that in a certain number of my cases degeneration and atrophic changes have been established, which at present would be recognizable only in case of operative removal.

To gain experience has been slow work, but after nine months of groping along in a problem, clear enough in its theoretical statement but beset with difficulties in its pioneering medical applications, I can but feel, in justice to Dr. Beard, that the medical profession owes it both to him and to themselves to give this method an exhaustive trial in hospitals and in the hands of specialists thoroughly equipped.

The Theory.—Dr. Beard believes that the cancer cell differs from other cells solely in the characteristic that it is a latent and aberrant germ cell unmodified as it should have been in the ordinary course of the development of the embryo. It is, thus, not a somatic cell, but one which in the life cycle of the development of the embryo, should have "degenerated" and passed out of existence. The thing that should have destroyed it, at about the sixth week of the life of the embryo, is the pancreatic juice from which trypsin is extracted. Certain of these germ cells, undestroyed by the pancreatic juice of the embryo, become located in various out-of-the-way corners of the growing human being, and later on, under favoring circumstances, propagate themselves and thus produce what we call cancer. Ergo, administer pancreatic juice hypodermically and in excess to the patient to destroy these "germ" or cancer cells, and also administer pancreatic diastase (amylopsin) independently of the proteolytic and fat-splitting ferments (trypsin and lipase).*

Preparations of Pancreatic Juice and Method of Treatment.—I have gathered most of my initial information from communications of Dr. Beard and from Mr. B. T. Fairchild. The preparations are: injectio trypsini, injectio amylopsini, lotio pancreatis, trypsin powder, holadin, lotio pancreatis, etc., etc.

The trypsin injection has been used in varying strengths and over varying periods of time, so that no very exact procedure can be given. I begin with five minims, increasing by five minims daily up to 20 minims. I was early met by a number of instances of severe reaction, but, on the whole, have found it advisable to give doses as large as recently advised by Dr. Beard, viz., 20 minims daily. In certain cases, when tolerance is fully established, more may be safely given. Dr. Beard assumes that after a certain time the cancer cells of the tumor die, and that their removal must be promoted by the use of the injectio amylopsini, a pancreatic diastase devoid of the proteolytic (trypsin) and fat-splitting (lipase) ferments. Indeed, Dr. Beard lays much stress upon the amount and the time of administration of the pure diastase in contradistinction to the trypsin in certain contingencies clearly explained by himself. Much clinical experience is yet needed to establish a dosage of these ferments alone or relatively to one another. This must be regulated by long clinical familiarity with the reac-

*The reader who would investigate this theory in detail can consult Dr. Beard's articles, namely, Embryological Aspects and Etiology of Carcinoma, *Lancet*, London, June 21, 1902; Problems of Cancer, *Lancet*, October 29, 1904; The Cancer Problem, *Lancet*, February 4, 1905; Are the Problems of Cancer Insoluble? *Medical Press and Circular*, December 20, 1905; The Action of Trypsin Upon the Living Cells of Jensen's Mouse Tumor, *British Medical Journal*, January 20, 1906; Trypsin and Amylopsin in Cancer, Medical Record, June 16, 1906. Also articles by Dr. C. W. Saleeby, The Coming Conquest of Cancer, *Harper's Weekly*, March 3, 1906, and Cancer—Can It Be Cured? *McClure's Magazine*, August, 1906.

tion of the patient and the reaction set up in the tumor itself.

These reactions in some cases are by no means minimal in character. As to the constitutional reaction, I have seen a dose of five minims produce rigor, followed by increased temperature, nausea, vomiting, pain in the back, drowsiness, high arterial tension, etc. This however, is exceptional, and tolerance is soon established. As to the local reaction, the tumor itself, when upon the surface, in some instances may be seen within six hours to become red or purple, turgid, and hot to the touch, while the patient complains of pain or of a "gnawing" sensation. In cases where reactions occur both constitutional and local symptoms subside in a few hours and the patient is ready for another treatment. No detriment to health ensues; on the contrary, in most instances, improvement of the general nutrition is noticeable, at least in cases not subject to profound and final cancer cachexia. As it is not our purpose to analyze either the theory, the practice, or the symptoms produced, but merely to present clinical results as a sort of provisional report, I will at once present some cases from which deductions may be drawn.

Cases from Private Practice.—The immediately following cases constitute instances in which trypsin has been used for a sufficient length of time to give indications as to what it may do. Cases recently put under trypsin, or those who have had but few injections, are excluded from the present report.

It will be seen, however, from a perusal of the records that, as has been said, most of them were hopeless at the time of beginning the use of trypsin.

It will be observed also that some cases suffered from rigor and fever reaction when trypsin was first begun. In the majority of cases no such reaction was observed, but when observed it must be interpreted as a favorable sign due to the absorption of the attacked cancer products.

Case I.—Miss K. E. H. July 3, 1905. Referred by Dr. Edw. W. Peet. Primary carcinoma. About one year ago noticed a small lump in the breast. The patient refused a radical operation and permitted the lump only to be removed. Within three months discovered another lump. Carcinoma determined by microscopical examination of the first tumor.

Present Condition: A massive involvement of the entire mammary gland with chains of infected lymphatics extending to the axilla and enlarged axillary glands. Advised preoperative *x*-ray for six weeks to two months and then operation. Patient firmly declined operation. The patient received 32 *x*-ray treatments extending over a period of seven weeks. The gland had reduced one-third in size, the tumor was freer, and absolutely every sign of lymphatic infection had disappeared. Again I urged operation at this favorable moment, even if again a limited one, but to no avail. Patient ceased treatment.

April 12, 1906, about eight months later, the patient reappeared. The disease now involved the entire skin over the gland and neighboring skin lymphatics. It was exceedingly hard and of a scarlet red color. Operation again advised strenuously, but refused. I then determined to begin the use of trypsin.

April 27. Injected five minims of trypsin diluted with ten minims of sterilized water into the tumor. The tissue was so hard that a strong needle could be inserted only with considerable force. The next day the breast was much redder and sorer.

This is the only time I have injected into the tumor itself. This method is not advised by Dr. Beard. In all subsequent treatments the trypsin was inserted into the thigh well beneath the skin, exercising great care to sterilize the needle. Tenderness at the site of the insertion of the needle usually ensues as well as some heat and swelling. These symptoms subside without abscess but each locality is to some extent reexcited by each new injection, though made, of course, in a new locality. Gradually the little tumefactions disappear.

May 4.—Injected five minims of trypsin into the thigh. Within six hours a severe chill developed, continuing off and on for four hours, succeeded by fever and then comparative comfort but with malaise lasting throughout the next day. Within twenty-four hours intense pain developed in the breast tumor and it was violently inflamed. It was dusky red, hot, and swollen. Within forty-eight hours the tumor showed signs of shrinkage. The injections of five minims were continued three times a week, followed each time by chill, fever, and profound feeling of weariness, which soon wore off.

An entry of May 18 adds further symptoms frequently observed in this case. The injection was given at 12 o'clock, noon; at 7 o'clock chills began and continued off and on about every fifteen minutes for about two hours. Then severe febrile reaction. No headache. Pulse slow and weak. About 10 o'clock experienced excruciating pain upon urination with frequent and intense necessity to void the urine during the entire night. She also had frequent diarrhea. The urine was yellow, like mustard water, and likewise the feces. This was due to some action of the trypsin unknown to me. The next day she "felt sick all over." Intense pain with heat, redness, and swelling developed in the tumor. It felt as "if it was all drawing up." This pain lasted all day and the breast ached all the next night.

May 20, two days later, the breast was decidedly shrunken. The nipple which had been intensely hard was soft and not so much retracted. Narrow chains of swollen lymphatic glands leading to the axilla and enlarged lymphatic glands in the axilla had disappeared.

May 26.—Patient had received about nine injections by this time, suffering after each one about as above described. Injectio amylopsini was now given, five minims, to absorb destroyed material and combat untoward symptoms, as advised by Dr. Beard. This caused intense pain in the breast for about twenty-four hours as well as pretty much the same, though less severe, symptoms as the trypsin. The trypsin was continued three times a week, increasing the dose up to ten minims. Both trypsin and amylopsin were used throughout the months of June, July, August, September, and October, and often without a reaction of chill and fever.

About October 15 the patient consented to operative interference. The cancerous breast had become drawn upward into a shrunken compact and hard mass of dusky red color but showed no signs of breaking down. The operation was performed November 3 by Dr. Wm. S. Bainbridge. Cancer nodules were found running along the lymphatic system beneath both the pectoralis major and minor and even involving the edge of the latissimus dorsi. A cancerous mass surrounded the subclavian vein, which was with difficulty dissected out. In fact cancer was disseminated over a wide and deep area of the affected side of the thorax.

This case is quoted somewhat in detail in order to point out the sort of reaction which at the worst and at the most may be expected. Of my thirty

cases treated, decided reaction of this nature has been exhibited in quite a number. Referring to these symptoms, Dr. Beard classifies them as nausea, vomiting, pain in the back, drowsiness, albuminuria, high arterial tension, edema, etc. He believes that these symptoms, which certainly are not generally present, bear some resemblance to eclampsia and are due to a like cause, namely, the products of the degenerating tumor. The signs of improvement noted in many cases are, cessation of pain, improved health and general appearance, diminution of discharge, if present, and a shrinkage and softening of the tumor mass. The dead tumor may become encapsulated and operation may be required to remove it.

Following is the report, dated November 23, 1906, made for me by Dr. H. T. Brooks, pathologist in the New York Post-graduate Medical School and Hospital, upon the tumor removed:

"Microscopic examination of the carcinoma mammæ removed from Miss K. H., showed that by far the greater portion of it was composed of extremely dense fibrous connective tissue with a very highly refractive and glistening character, strongly resembling the fibrous connective tissue change noted in breast tumors subjected to the *x*-ray. The carcinomatous (epithelial) elements were only scantily present in this tissue, and more in the form of a diffuse infiltrate than in alveolar arrangement. The cells seemed to have undergone some degeneration, as they were granular, partly distintegrated, and stained very poorly even after long action of hematoxylin. The connective tissue seemed to be encroaching upon them, as there was considerable round-celled proliferation in these areas. This character of tissue was confined chiefly to the peripheral portions of the tumor. In the central parts and at the base or attachment to the chest, the alveolar arrangement of the cells was very decided and distinct, and the connective tissue separating the alveoli was in broad, very dense, glassy, quite homogeneous bands unoccupied by epithelial cells. Here also the epithelial cells were degenerated, but much more markedly, especially in the centers of the larger alveolar nests where large areas had undergone coagulation necrosis. While such coagulation necrosis is not at all common in the central portions of carcinomata alveoli, it was so widely distributed as to be quite striking. The great density of the tissue throughout and the decided degenerative changes in the epithelial cells gave the impression that atrophy of the carcinoma elements had occurred and been followed by great contraction and condensation of the fibrous connective tissue stroma."

A remarkable feature of this case was the shrinkage of this breast into an intensely hard, compact mass and its contraction upward until upon a level of several inches above its mate. Dr. Brooks assures me that had the process outlined in his report continued the result would have been such marked condensation of the fibrous connective tissue as to have made it very difficult to determine the carcinomatous nature of the growth. In fact the tumor at the time of the operation was progressing to a point where its pathological nature would be considered simply as scar tissue. While ordinarily in such a tumor we have overgrowth, in this tumor we have atrophy of the cells and have the contracting fibrous tissue of a scar. The finality of this process would have been a carcinomatous breast (involving inclusively its skin envelope) which had entirely disappeared—which had become, in short, absolutely cured, and by a process strikingly illustrated in Dr. Brooks' report.

The above case is a remarkable one, clinically, on account of the decisive action of trypsin upon the cancer, and pathologically on account of the opportunity which the operation presented of making a microscopical examination of the actual changes produced by trypsin in cancerous tissue. If, by the judicious management of trypsin and amylopsin such changes as this can be repeated in the cancerous tumor, we shall be obliged to admit that a new era has opened in cancer treatment and a great boon offered to the cancer sufferer. It is only fair to Dr. Beard to state that the outcome here demonstrated is exactly what he predicted.

Case II.—Mr. G. B. R. Age 48. December 27, 1905. Referred for *x*-ray treatment by Dr. Louis Stimson. Beginning December 27, 1904, noticed a small hard lump growing in the upper portion of the parotid gland close to the ear. The lump increased in size and occasioned a good deal of pain. Soon afterwards another small lump appeared on the chin on the other side of the face. In May, 1905, submitted to laparotomy for "inflammation of the gall bladder." It is believed that probable malignancy existed at that time at the site of this operation. In October, 1905, he was operated on by Dr. McKechnie of Vancouver, B. C., and the parotid tumor was removed. December 4, 1905, Dr. I. Leone Adami, Professor of Pathology and Bacteriology in McGill University, reported that the tumor removed was sarcoma. Patient presented himself for treatment having a small tumor at the site of the former operation in the parotid and two painful sarcomatous nodules beneath the skin and adherent to the lower fascia, one on the abdomen and one on the back. These nodules rapidly diminished in size under *x*-ray treatment and were removed by Dr. Louis Stimson January 6, 1906. The patient left February 23, 1906, for the West, but showing pronounced signs of cachexia. He was weak, languid, and sallow.

April 14.—Patient returns for treatment. He looks ghastly, gray, and debilitated. His parotid tumor persisted and during his absence he had nine sarcomatous nodules cut out from different parts of the skin. He complains also of severe pain in his head and sleeplessness, and other symptoms from which a sarcomatous nodule in the brain is suspected. A single sarcomatous nodule exists on the dorsum of the foot. This the patient says he has retained in order to keep "tab on me."

April 16.—Began injectio trypsini 5 minims, increasing. As no *x*-ray or other treatment was used, the immediate subsequent effects were undoubtedly due to trypsin. On April 21 the tumor on the top of the foot had entirely disappeared, the scar over the parotid which was thick and turgid had flattened out, and the skin was flexible. The action on all of the cicatrices remaining after his many operations was peculiar. Within a few hours they looked swollen and angry red, and within a day or two the inflammatory action subsided and the cicatrices appeared to be perfectly normal. April 21. Trypsin 8 minims. April 22. Patient suffered to-day a severe epileptiform seizure lasting several minutes, with loss of consciousness and subsequent loss of memory for several hours. At the same time the various cicatrices upon the body were greatly inflamed. I suspect that the seizure was due to the same reaction on an intracranial tumor as had occurred in the visible scars. The trypsin was discontinued or reduced in amount for some time. New nodules now appeared on different parts of the body and again subsided under the use of trypsin, but in the meantime the patient's cerebral condition grew worse and worse. His articulation failed, he suf-

fered attacks of great pain in the head, and periods of partial collapse. Again there would be days when he appeared to be recovering and when he could find words and express himself with clearness. At the same time the headache had diminished. June 1. Consultation with Dr. C. L. Dana, who coincided with the diagnosis of sarcoma of the brain. The trypsin injections had been diminished to 2 minims and were given infrequently by reason of feeling one's way along according to symptoms. June 20. Consultation with Dr. Abraham Jacobi. Patient in a state of semistupor. The nodule on the side of the face at the site of the scar increased in size, a new nodule had appeared upon the shoulder, a nodule on the left side remained about the same, while undoubtedly the tumor in the brain was increasing in size. It would be of no value at this point to give details as to its location, etc. On June 2, after consultation with Dr. Jacobi and at his advice, I began the hypodermic use of arsenic, but with no modification in the progress of the disease. On July 4 the patient died.

While the patient's life was not saved in this case by the use of trypsin, still it is evident that a decisive action in the sarcoma was secured, that a sarcomatous nodule was caused entirely to disappear, and that other nodules were markedly reduced in size. It is deeply to be regretted that a cerebral complication developed, for otherwise the trypsin might have been pushed to much greater limits. It is obvious that while the reaction observed was undesirable within the closed cavity of the skull it would have been of less consequence in looser and freer tissue. The case teaches at least that trypsin causes reaction and diminution in disseminated sarcoma.

Patient received in all 27 trypsin injections varying from 2 minims to 10, but on an average 5. Also he received injectio amylopsini at times.

Case III.—Mrs. M. F. Age 47. May 1, 1906. January 4, 1906, laparotomy by Dr. E., who removed a large abdominal cancerous mass involving all neighboring tissues. The wound did not heal entirely and a recurrent tumor as large as the closed hand was apparent on palpation. The case was evidently hopeless. Was submitted to *x*-ray and fluorescent treatment merely to prolong her life and to ease the patient. In addition to *x*-ray the patient was given holadin 8 grains 3 times daily.

May 4. Began injections of trypsin. First injection 5 minims. Six hours later it was followed by chill and fever. The patient was treated at her home, receiving *x*-ray and 37 injections of trypsin. The tumor where presenting externally exhibited local reaction. She died August 6.

Case IV.—Mrs. J. L. B. Age 50. February 13, 1906. Presents herself with the entire breast thickened and infiltrated with carcinoma with enlarged glands in the axilla and several nodules in the skin. Loss of flesh and cachexia. Extensive retraction of the nipple and surrounding tissue. Practically the entire gland involved. Under *x*-ray and fluorescent treatment retraction diminished, the breast gland cleared up from induration, the axillary glands and skin nodules disappeared, and the disease was reduced to a single small tumor, perhaps one inch in diameter.

May 21. Trypsin was begun merely with a view of helping along, if possible, her splendid progress. Trypsin injections, together with injectio amylopsini have been continued as follows: May, three times; June 8 times; July, sixteen times; August, thirteen times; September, thirteen times; October, thirteen times, and continued in November. After the first injection of trypsin of five minims, within an hour she felt "creepy-like sensations, and almost a chill, and very miserable." Could eat no dinner, felt sick at her stomach, and weak the next day. These feelings gradually passed off, though causing a good deal of looseness of the bowels for several days. The *x*-ray also has been continued steadily with fluorescent substances. The patient has been advised that a general operation is the usual procedure; I have also advised her that a limited operation for the removal of the tumor is now, under all circumstances, desirable. Such a limited operation can undoubtedly be performed with a minimum danger of recurrence, whereas before treatment the maximum operation would undoubtedly have been followed by subsequent cancer. After the first few injections the remaining ones, even when increased up to twenty minims, were well borne. Owing to the pressure of other medical advice and the views of members of her family, I have finally advised the patient to be operated upon, in which case we shall probably find the same condition of the cancer mass as in Case I, viz., progressive atrophy.

Case V.—Mr. R. C. H. Age 54. April 18, 1906. Referred by Dr. Calvin Adams. Extensive epitheliomatous disease of the lower jaw bone and base of the tongue, already progressed to a point where no operation was possible and where the patient's death was only a question of a short time. Took large quantities of narcotics. Patient derived great comfort and experienced improvement under the use of the *x*-ray.

April 21, began trypsin, eight minims, increasing at times to twenty, and gave in all eleven injections.

June 1. The patient experienced a severe hemorrhage and ceased all treatment, the case being apparently hopeless. Patient died August 5. The advanced stage of the case and the comparatively small number of injections render it impossible to draw any deductions of value.

Case VI.—Mrs. E. M. Age 57. October 18, 1904. Referred by Dr. A. L. Macken. Extensive epithelioma of the lower eyelid with cicatrices from frequent operations. Under *x*-ray treatment for about three months patient was entirely cured, but at the end of four months four new cancerous nodules appeared upon the cheek two inches away from the original site of disease in the end of two radiating cicatrices remaining after the original operation. These tumors the patient neglected for nine months, and finally again returned for treatment. The extensive cicatrix resulting from the cure by the *x*-ray remained entirely sound and exhibited no sign of recurrence. The use of the *x*-ray was now unavailing, for each treatment set up acute inflammatory reaction, a thing frequently noticed by me when the tissue has been treated for a long time with radiation. Various glandular extracts were tried by the mouth, including the thyroids, but with no result.

October 1, 1906. Began trypsin and amylopsin, and gave eighteen injections extending over a period of six weeks. As the patient had four cancerous nodules about the size of a large pea upon the eyelid and an ulcer, she constituted a good case to observe and study. No changes whatever in the growth took place during the six weeks of treatment, and other measures were resorted to. I propose soon to try trypsin in this case in the light of further experience.

Case VII.—Mr. A. P. Age 65. April 10, 1906. Referred by Dr. William F. Fluhrer. Cancer of the bladder. Advanced case. Passed blood fre-

quently, severe pain, and pronounced cachexia. Treatment *x*-ray, fluorescin and radioactive water. April 25, commenced the use of holadin, eight-grain capsules, one three hours after meals. Improved very decisively during the next month, and was able to give up large doses of narcotics.

May 14. Began the use of injectio trypsini five minims. Patient received six injections in May and seven in June. June 27 the record reads: "Feels great muscular weakness. Experiences frequent urination, twenty or thirty times daily. No appetite. Looks worn and tired. Will omit trypsin for a while." Patient soon ceased treatment, and died in July.

Case VII.—Miss M. W. Age 61. Patient had slow-growing carcinoma of both breasts, commencing in 1892. In May, 1902, came to my office. Refused operation. Was put under *x*-ray treatment for one year, and remained almost well until September, 1904, when she again returned with an eruptive condition on the thorax which was evidently disseminated carcinoma of the skin. This condition gradually increased and involved the entire front of the thorax as well as the axillary lines. May 14, 1906, patient was in a deplorable condition. She presented the appearance of a typical *cancer en cuirasse*. Numerous nodules from the siz of a pea to the size of a large marble existed, as well as large patches where these nodules had become confluent. Cancer nodules could be found scattered almost anywhere over the body. In this case trypsin was given as a last resort. The first injection of five minims produced a slight chill and a slight fever. Trypsin treatment was continued regularly seven times in May, ten in June, eleven in July, ten in August, eight in September, seven in October, and continued in November. The injectio amylopsini was given at due intervals. The effect of the treatment was to produce a decided amelioration in the progress of the disease. A great number of cancer nodules disappeared entirely, and even confluent areas cleared up of induration and coloration and present a condition of normal skin. It would be too much to expect a cure of such a case by any known remedy, but it certainly is a fact that the patient's condition has been greatly improved.

Case IX.—Mrs. C. M. R. Age 66. October 25, 1906. Referred by letter from Dr. John Beard of Edinburgh. One year ago last April first noticed bearing down and straining and often passing a little blood at times of going to stool. Condition was thought by the family physician to resemble at that time chronic dysentery. This condition continued steadily, growing worse, up to August, when the patient consulted Dr. A. H. Laidlaw of New York. Dr. Laidlaw gave it as his opinion that she was suffering from a rectal cancer of about the size of an orange. He found that merely a small canal passed through the center of this tumor. Dr. Laidlaw's opinion was verified by Dr. Hollister of Newark, the patient's family physician. The patient, after taking cathartics for a long period, had been advised to take rectal enemata with a long tube every other day, and in this manner has kept herself fairly comfortable, but the present symptoms indicate a further closure at the point of stricture. Examination revealed precisely the conditions above outlined, namely, a large rectal tumor situated three or four inches up the rectum and a small canal running through its center. Patient lives at a distance and can make but three visits a month.

Treatment: Began trypsin injections, quickly increasing to twenty minims, and lately to thirty, giving in all thirteen injections to date of November 22. Just beginning amylopsin. Patient reports that she feels improvement in various directions. In the first place generally she feels better, in the second has a less collection of gases in the abdomen and less rumbling and general distention. Also lessened necessity for using the enemata and the ability just developing to go to stool in an ordinary manner. Certainly her general health has improved.

[illegible] *Graduate Medical School and Hospital.*—The administration of this remedy in my clinic at the hospital has been under my direction in the hands of Dr. W. Parker Worster, instructor, who has given most careful attention to every detail, and furnished the specific data for this report. Most of these cases, as has been stated, were inoperable and beyond all hope of cure by any known method. Also most of them received *x*-ray treatments, for the reason that they had been accustomed to them at the time of beginning the use of trypsin, and if the *x*-ray had been omitted it would have been difficult to secure their attendance. The *x*-ray was shortened in time and subordinated to the trypsin. These patients were seen three times a week. The irregular attendance and frequent disappearance of this class renders impossible a conclusive report in some instances except as to obvious improvement.

Case X.—Mrs. McK. Age 48. May 14, 1906. Referred to the clinic by Dr. J. N. West. Epithelioma of the nose. One year duration. Tissue involved about one inch in diameter. Disease consisted of a deep and angry looking ulcer with raised edges and had been existing for several years and incurable by numerous other measures. Received twenty-five trypsin injections, ten minims, increasing rapidly to twenty. Ceased treatment August 13, 1906; completely cured to date.

Case XI.—Mr. O'K. Age 36. April 27, 1906. Referred to clinic by Dr. Morton. Epithelioma of the nose involving the entire left side, extensive destructive areas. Thirty years standing. Disease rapidly progressing. Had had five operations for removal without any success. Began trypsin injections. Several produced chills, trembling and hot flushes, but as a rule it was well borne. The ulcer also often exhibited a local reaction of swelling and increased discharge the next day after each injection, whether of trypsin or of amylopsin. The dose was carried up to twenty minims, and the patient received in all fifty-one injections, including ten of amylopsin, up to November 9. Patient made remarkable improvement at one time, especially during the use of the amylopsin, and the disease is now progressing steadily toward a cure.

Case XII.—Mrs. O. Age 46. Referred by Dr. Thompson Sweeny. Carcinoma of the uterus, two years duration. Admitted to the hospital for operation, but pronounced inoperable. Disease involved bladder and rectum and produced incontinence of urine. Brought to the clinic in a carriage and was carried to our room owing to extreme weakness and cachexia. In this case the patient was given alternating doses of trypsin and amylopsin, twenty minims of each at each dose. At the same time she received ten minutes of *x*-ray. Patient received eighteen injections up to November 9. She made remarkable improvement in general health. In about five weeks she was well enough to walk easily to the hospital for treatment, and the incontinence of urine had nearly ceased. Her general cachexia disappeared. As to her exact present condition Dr. Sweeny reports, November 21: "Local condition not im-

proved as to size and extent of growth, parts little less indurated, bladder is fairly continent. General condition of patient greatly improved, cachexia gone, color in face again, increase of weight, appetite better. Patient was bedridden when treatment began. Patient can walk about streets at present. She could hardly have lived five months more at the time of beginning treatment."

Case XIII.—Mrs. H. Age 42. September 21, 1906. Sent to the clinic by Dr. F. A. Dorman. Carcinoma of the uterus. Had been operated upon by Dr. Boldt. Disease had existed in aggravated form for two months. Very much exsanguinated from frequent hemorrhages, debilitated and cachectic. Suffered much pain. Has received sixteen injections of trypsin, alternating with amylopsin, up to date of November 12.

In about one month exhibited very great improvement in strength and in general appearance. Could walk well and attend to her washing and ironing without fatigue, the first time in seven months.

November 22. Examined by Dr. Boldt, who reports as follows: "Mrs. H.'s condition is quite encouraging. The disease certainly has not made further progress, and the vesicovaginal fistula which occurred in consequence of a slough after my cautery operation is seemingly closed. Please do push the treatment. It is very interesting to see the results."

Case XIV.—Mr. J. S. Age 49. September 19, 1906. Two operations by Dr. S. Sherwell of Brooklyn. Epithelioma of left cheek of five years' duration. Ulceration size of the end of finger, but very deep, and surrounded by extensive induration. During last five years had had other operations with recurrence in each case. Received twenty injections up to November 12, trypsin and amylopsin alternating. After the third injection improvement set in, and the patient's disease has progressively healed up to date. No ulcer now exists and no induration remains. The resulting scar is excellent, but shows a deep depression. Cured to date.

Case XV.—Mrs. S. Age 36. June 16, 1906. Referred by Dr. Thurston Lusk. Epithelioma of face, external to the right eye. Ulceration about two and a half inches in diameter, very deep, and existing for three years. Had had a variety of treatments. Received twenty-one injections to date of September 10. No constitutional reaction. Patient obliged to discontinue treatment by reason of intercurrent illness. Not very much improved in her condition. Was excessively anemic and cachectic and took treatment very irregularly.

Case XVI.—Mr. M. S. Age 66. May 23, 1905. Referred to the clinic by Dr. Hornby of Brooklyn. Epitheliomatous ulcer about half an inch in diameter just below the left lower eyelid. No operation. Received *x*-ray treatments off and on for four months, with little benefit. Put under trypsin treatment. Received twenty-four injections and about three of amylopsin up to October 14. Patient was most irregular in attendance and received about four treatments a month on an average.

November 23. Patient almost well. Ulcer one-third of former size. Flat and even with the cheek and induration all disappeared.

Case XVII.—Mrs. R. Age 36. May 21, 1906. Referred to the clinic by Dr. Thompson Sweeny. Scirrhus of right breast, four years' duration. Refused operation, which was often advised. Had been under *x*-ray treatment for seven months. The tumor decreased under this treatment nearly two-thirds in size and had reached a stationary stage. Trypsin begun. Received but nineteen injections, owing to her irregular attendance at the clinic. November 14 patient reports that she had become pregnant and was in great distress at the possibilities of the cancerous tumor of her breast. She was referred for advice to Dr. J. N. West, who advised, with our hearty assent, the removal of the breast. Case uninstructive as regards trypsin.

Case XVIII.—Mrs. S. Age 48. September 24, 1906. Referred from skin clinic by Dr. Thurston Lusk. Epithelioma of inner canthus of left eye about half an inch in diameter. An open ulcer. No operation. Came very irregularly. Had three injections of trypsin, alternating with three of amylopsin, over a period of about one month. Ulcers almost healed when last seen.

Case XIX.—Miss M. D. Age 46. May 14, 1906. Referred to clinic by Dr. Thompson Sweeny. Carcinoma of uterus, extensively involving bladder; great edema of both legs. Inoperable. Disease complicated with nephritis. Assisted to the hospital and lifted to the table. A hopeless case, and in great agony. Received nine injections. In the course of the first week showed remarkable improvement. Dr. Sweeny reports that at the end of three weeks "the incontinence of urine ceased, the swelling of the feet and of the legs, which were enormous in size from the feet to the pelvis, became reduced at least one-half, and the skin of the legs, which had been white, tense, and glistening, began to look normal and became loose." She disappeared from clinic and died of kidney disease. The action of the trypsin in reducing the edema of nephritis in this case is worthy of note, though possibly the edema may have been due to pelvic pressure of the carcinomatous growths. Dr. Sweeny reports, November 21: "Patient's general condition undoubtedly improved during the four weeks while under treatment. From being bedridden she was able to be abroad."

Case XX.—Mr. P. B. Age 73. May 21, 1906. Referred to the clinic by Dr. Charles W. Allen. Epithelioma of right side of face in front of right ear, measuring three by four inches and deep. Eight years' duration. Case was distressing and hopeless. Had frequent hemorrhages. He had improved slowly under *x*-ray. Trypsin was begun May 21. Immediately on beginning treatment the character of the sore changed. The submaxillary glands were extensively involved, and filled up the submaxillary space on the right side. The glandular swellings disappeared almost entirely. Patient received in all fifteen injections of trypsin up to July 2, and then disappeared from clinic. His attendance was extremely irregular since he lived at a distance. When last seen his general health had improved and the ulceration was smaller, but still deep, and by no means cured. The hemorrhages had ceased. In view of the favorable effect of trypsin it is greatly to be regretted that this case could not have been more closely followed up.

Case XXI.—Mr. R. W. Age 44. June 1, 1906. Referred to the clinic by Dr. Rauth of Brooklyn. Osteosarcoma of the left ramus of the lower jaw, of three years' duration. Great enlargement of the bone, while also the submaxillary glands were so much enlarged that the contour of the neck on the affected side was on a level with the face. Angle of the mouth was drawn downward. The swelling of the glands diminished two-thirds. Up to July 13 patient received eighteen injections, ten minims of trypsin, when great improvement began to manifest itself. The tumor reduced in size. July 27 trypsin increased to twenty minims, and tumor continued progressively to diminish in size. Patient disap-

peared from the clinic and no further report at present can be given as to his condition.

Case XXII.—Mrs. B. Age 54. May 23, 1906. Referred to the clinic by Dr. Jenkins of Brooklyn. Sarcoma of right shoulder, frequent and profuse hemorrhages, pronounced incurable by several physicians. Disease involved the top of the shoulder over eight inches anteroposteriorly and five inches transversely. Began ten minims of trypsin May 23 with pronounced and satisfactory results. The profuse hemorrhages ceased entirely for a time, but later on returned in a slight degree. The patient's tumor at one time became infested with maggots, which were removed by aid of bichloride solution. Patient suffered from chills following several of the injections. Received in all eleven injections, irregularly administered. The effect upon the disease was discernible by diminution of pain and lessening of hemorrhages, but the patient died June 22.

Case XXIII.—Mr. E. Van B. Age 80. October 12, 1906. Epithelioma of right side of nose. Five years' duration. Extensive destruction of tissue, removing the entire left side of nose, producing a large and deep ulcer. Desperate case. Inoperable. From October 12 to October 24 received six injections of trypsin and amylopsin, with evident improvement, especially in his general health. Patient disappeared from clinic and no further report can be made.

Case XXIV.—Wm. T. Age 48. Referred to the clinic by Dr. Morton. May 18, 1906. Epithelioma at the end of nose, involving the entire organ up to the bridge. An open ulcer and destruction of tissue of the septum and upper lip. Three years' duration. Inoperable. Received twenty injections of trypsin up to August 20. Improvement manifested itself early, and was maintained, but the patient ceased injections at latter date. He had developed an abscess from the trypsin injections and was fearful of a further experience of that kind.

November 20. Patient returns. Diseased area no longer causes him pain and is reduced in size. Case is improving.

Case XXV.—Mrs. McK. Age 57. Referred to clinic by Dr. J. N. West. June 21, 1906. Extensive carcinoma of uterus. Six months' duration. Inoperable. Severe hemorrhages. From above date to November 19 inclusive received sixty-two injections of trypsin, alternating frequently with amylopsin. She exhibited a good deal of improvement in general health, and the lesion is so much improved that the patient is unaware of its presence. Patient examined again by Dr. West November 26, who reports that while up to within several weeks very great improvement was manifested, during the last three weeks the disease again exhibits signs of activity and the patient is not so well. The trypsin in this case should be pushed to a larger dosage, and will be.

Case XXVI.—Mr. J. C. C. Age 56. May 23, 1906. Referred by Dr. David Webster. Epithelioma of inner canthus of right eyelid and extending down upon the nose. Had received *x*-ray treatment with some improvement, also radium. Began use of trypsin May 23, and received up to September 27 twenty-five injections of trypsin, on an average of six injections monthly. But little progress was made.

Case XXVII.—Mrs. S. S. Age 38. May 21, 1906. Referred to clinic by Dr. William B. Coley. Lupus of the upper lip and cheek and nasal septum and upper maxillary bone including the hard palate. In Februrary, 1905, was operated on at Roosevelt Hospital for lupus of the cheek and lips. Following the operation the disease increased with great violence until it involved the upper maxillary bone corresponding to the four incisors and the two canine teeth running backward to a considerable distance on the hard palate. Taken together, this invasion produced a round tumor mass which caused a pronounced projection of the upper lip. Received trypsin injections, twenty minims, three times a week. At the end of the first month the tumor reduced very greatly in size, and at the end of the second month the reduction was still greater and pieces of bone from the hard palate either fell out or were picked out by the patient. About the fourth month no evidence of a tumor could be discovered. The nose and upper lip had fallen in, producing great facial deformity. At the time of present writing, about the end of the fifth month, while it cannot be said that the patient is entirely cured, for there remains a small patch of disease on the edge of the roof of the mouth, still the disappearance of the large tumor has been most remarkable. The patient can introduce the finger easily into the hole in the hard palate, upward, and it would seem as if another month would complete the cure.

Case XXVIII.—Mrs. P. Age 24. May 1, 1906. Referred to clinic by Dr. H. J. Boldt. Carcinoma of rectum. Two years' standing. No operations. Inoperable. Received twenty-four injections, twenty minims, of trypsin and amylopsin up to October 15. The pain in rectum disappeared after the first few injections, and the relief was so great that patient asked for injections in preference to any other treatment. About July 6 the patient was so much improved that her attendance became very irregular. Has continued treatment off and on up to November 18, with continued improvement in general health.

Case XXIX.—Mrs. S. Age 42. June 11, 1906. Lupus vulgaris of left eye and nose. Eyeball had been removed and entire socket was a mass of disease, extending down upon the nose. Disease existing four years. Received twenty-one injections. On September 21, 1906, ceased treatment owing to intercurrent illness. At the beginning of the trypsin injections severe reaction of an inflammatory nature appeared in the ulceration, followed by profuse discharge and sloughing. The hemorrhages soon ceased entirely, the wound took on a healthy aspect, its edges contracted and turned inward, and healthy granulations appeared. The entire ulcerated area has closed in with normal tissue to about half its original size. Patient sends word that she will return to treatment.

Comments upon Above Cases.—1. Two of them, cases 10 and 14, severe cases of face cancer, are cured to date by the use of trypsin.

2. A remarkable process of retrogression by degeneration and atrophy of a carcinomatous breast gland to final and curative obliteration has been microscopically demonstrated in Case 1.

3. In all cases signs of amelioration in the progress of the disease have been observed.

4. Cases 1, 2, 3, and 11, among others, demonstrate beyond question that trypsin may produce local reaction in a cancerous tumor indicated by swelling, heat, pain, or increased discharge.

5. Cases 1, 2, 3, 4, and 8, as well as others not especially recorded among the hospital cases, demonstrate that trypsin produces constitutional reaction characterized by rigors, fever, pain in the back, sense of weakness, drowsiness, etc., but of temporary duration.

6. Cases 20 and 21 demonstrate that enlarged

glands associated with cancer have rapidly diminished in size under the influence of trypsin.

7. It has already been pointed out that these cases were mostly absolutely hopeless at the time of beginning treatment.

8. Rigors and increased temperature following within a few hours the injection of trypsin are an encouraging sign since they indicate that the cancer has been attacked by the trypsin. The symptoms are due to the toxic action of absorbed and destroyed cancer products.

9. Trypsin has a decided effect in reducing cancer cachexia and in improving the general health.

10. The result of the trypsin treatment in many instances, as notably in cases 12, 13, and others, demonstrates that even in severe cancer of uterus involving the associated pelvic organs the disease may be brought to a halt, so to speak, even if the patients do not eventually recover.

11. The use of trypsin has caused hemorrhages to cease and has alleviated pain.

12. It is a fact that the patients frequently refer their greatest feeling of improvement to the period of time when they are taking amylopsin following trypsin. An important, as well as a difficult, feature of the treatment, therefore, is reasonably to determine the proper time to administer the diastatic ferment as well as the requisite amount, following or during the use of the trypsin. It has seemed to me that the pure diastase (injectio amylopsini) had much to do with favorable results.

13. Weighing carefully the above cases, I have come to the conclusion that trypsin, if possible, should be used in larger doses than I have yet used it in most of them. Feeling one's way, for instance, from twenty to thirty minims daily for from four to six weeks, as advised by Dr. Beard, and then resorting to amylopsin. It is only lately (November 23), that I have been able to get a microscopical report (Case 1) of the actual effect of trypsin upon a cancerous tumor. This report has lent another aspect to the work and encourages me as it will others.

14. In all fairness trypsin deserves further trial, but I reserve an opinion as to its actual therapeutic value until I can speak from a larger experience.

19 East Twenty-eighth Street.

A CASE OF BRONCHITIS; WITH REMARKS ON COUGH AND THE PERFORATED ZINC INHALER.*

By BEVERLEY ROBINSON, M.D.,

New York

On the afternoon of September 24, 1906, I was called to see a patient, male, married, dentist, 62 years old. He was seated in a chair bent over on the bed, and, as he said, able to breathe at all only in that position. If he lay down he had intense dyspnea and constant cough. Even in the position in which I found him he had marked dyspnea and constantly recurring cough. I discovered, on examination of chest, that there were a few disseminated moist râles everywhere. The air, however, even on forced inspiration, entered the lung cells very imperfectly. Examination of throat negative. The voice was not notably hoarse. The heart action was rather weak—a soft-blowing systolic murmur at the apex. The pulse showed tension—about 90 to minute. Respirations, 24. Temperature under tongue, 102° F.

*Read at a meeting of the Practitioners' Society, November 2, 1906.

Patient told me he had been suffering from a bad cold during ten days previous. He had gone to the country a few days before and sent for the doctor, who gave him codeine frequently, and steam inhalations with benzoin. Wishing to see me, and being no better, he returned to the city, having been about three hours on train. I sent for trained nurse and prescribed liq. ammon. acet. and Apenta water for following morning, as the bowels were torpid. He vomited liq. ammon. acet. and I prescribed sp. ætheris nitrosi 20 gtt. every two hours in water.

September 25.—Apenta water had not moved him, so I ordered 5 grs. mass. hydrarg. and a castor oil enema (℥ss of oil), inhal. of tr. benz. co. frequently, Hoffmann's anodyne gtt. xx occasionally, and tablets of ipecac gr. 1-10 every half hour until nauseated. Soap liniment to chest.

September 26.—Cough constant and extremely fatiguing; unable to lie, except on stomach, and only for a few moments at a time. Temperature 101° F. Consult. with Dr. Delafield, who ordered fl. extract hydrastis gtt. xx with ipecac gr. 1-10 every three hours.

September 27.—Cough and dyspnea no better. Tried tablets one every four hours of digitalin gr. 1-100, strych. nitrate gr. 1-50, nitroglyc. gr. 1-100, and atropine sulph. gr. 1-150, in view of some weakness of pulse and concentrated and small quantity of urine—oxygen. Mustard poultices to back.

September 28.—Cough and dyspnea no better. After paroxysms of cough spat up small quantity of frothy and thick mucus. Prescribed every hour or two tablets of cubebs gr. 1-10, ammon. chlorid gr. ¼, licorice gr. 1-10, and heroin gr. 1-100 (Frazer's). Continue oxygen, heart tablets as required, iodine to chest. During night patient had symptoms of heart failure. Helped very much with tincture of strophanthus in tablet form, by mouth. Hypodermic of morphine, gr. 1-8, after consultation with Dr. V. H. Norrie.

September 29.—Expectoration became purulent, cough and dyspnea about same. Prescribed mist. glycyrrhiz. co. ℥i every three hours, fluid extract of coca ♏xx every three hours.

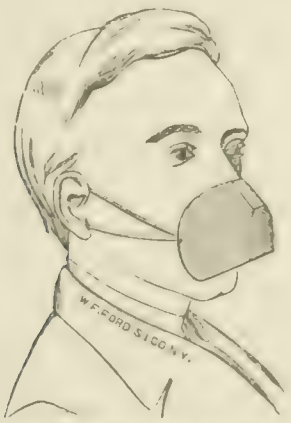
September 30 and October 1.—Abundant purulent expectoration, constant cough and dyspnea. Temperature 101° F., went to 103° F. (under tongue), evening of October 1. Sputa examined microscopically; showed numerous pus cells, no tubercle bacilli; urine, sufficient quantity, trace of albumen, good specific gravity, acid, a few hyaline casts. Blood: no malarial organisms; Widal not made; increase of leucocytes (17,500); normal number of red cells; normal amount of hemoglobin.

October 2 and 3.—Iodine to chest, stop mist, glyc-cyrrhiz co., as it nauseates slightly and gives headache; abundant purulent expectoration; cough constant; dyspnea perhaps somewhat less; can sit in upright chair with relative comfort; increase coca to ♏xxx every three hours; two minims of beechwood creosote with elixir of pepsin, properly diluted, three times daily, after food. Temperature, 99° F.; pulse, 90; respiration, 26. Allowed soft solids in great moderation, lithia water to drink, and a mixture of sulphate of soda, carbonate of lithia, and bicarbonate of potash every morning for bowels and general system. Patient is notably gouty, and has been to Carlsbad on two occasions. He is a very small meat eater, and lives principally on farinaceous food and vegetables.

October 4 and 5.—Creosote and pepsin continued; began use of perforated zinc inhaler with creosote, alcohol, and spirits of chloroform occasionally, and increasing duration gradually. After forty-eight

hours cough much better, dyspnea improved, sputa less in quantity and less purulent, patient could lie a little while on both sides, and breathe fairly well. In the early afternoon he felt much better, and came downstairs (October 5). Saw Dr. Janeway in consultation, who agreed with me that patient might go to the country with advantage the following day.

October 6.—Went to country in afternoon—three hours distant by rail; ordered to continue creosote internally and by inhalation, extract of coca and mixture with sulphate of soda. The diagnosis in this case was generalized subacute bronchitis, probable interstitial nephritis and arterial changes, with thickening, of gouty nature; heart somewhat hypertrophied and dilated with possible myocardial degeneration (patient is a man of large frame, corpulent); prognosis good, if rest is taken, and later a cure at Hot Springs of Virginia. Interest of the case for me is in the fact that, despite all rational treatment for many days (eight or nine), there was continuous cough, marked and distressing dyspnea, profuse purulent sputa, and great restlessness. After forty-eight hours of use of perforated zinc inhaler all these symptoms were much benefited, as well as pulse and heart action, and general condition. Creosote internally no doubt helped, and also coca and magnesia mixture, but the inhalations were especially useful.



The Perforated Zinc Inhaler.

It is worth while, therefore, to remember a simple instrument and simple treatment, which may notably relieve distressing cough and dyspnea, when other medication, inward and outward, are seemingly not very useful. The cough in this case, I believe, weakened heart, and thus helped to increase dyspnea, which aggravated patient's suffering.

Now that cold, blustering days have come, coughs and colds are very frequent, and to treat them pleasantly and efficiently—and, of course, safely—is no mean part of our art. Formerly I made use in very many cases of the perforated zinc inhaler, and then for several years I abandoned its use, except in occasional instances; why I cannot say, because I always found it useful and efficient in allaying cough from laryngeal and bronchial irritation, or inflammation. Within a brief period I have again taken up the use of the perforated zinc inhaler, and, feeling as I do at present, I do not believe I shall abandon its use readily. The solution employed and advised is equal parts of beechwood creosote, alcohol, and spirit of chloroform. From 5 to 15 drops of the liquid may be dropped on the sponge of the inhaler and renewed one or more times daily, as required. At first the inhaler should be worn a few moments at a time and reapplied every hour or two. Later, after a few days, a week or more, the inhaler may be worn continuously one or more hours during the day, and even night. I am also confident that in every stage of pulmonary phthisis the perforated zinc inhaler will be found valuable, not only to supplement other curative measures, and even the internal use of creosote properly given, but also because of itself it is directly curative. I regret extremely that more than one prominent authority has latterly endeavored to neutralize a judicious faith in the utility of creosote medication in pulmonary phthisis, basing judgment on the pathological conditions present. I, for one, recognize no such objections as valid. Creosote vapors unquestionably penetrate air cells unless completely blocked, and when they cannot penetrate certain diseased areas, at least they modify favorably a large part of the bronchial tract, and doubtless prevent in this way, if no other, the wider dissemination in very many instances of the tuberculous infection. To those who have a doubting mind I would here refer them to an able and convincing paper written by Dr. Austin Flint, Sr., in the *New York Medical Journal*, December 8, 1888, p. 617, entitled "Creosote in the Treatment of Phthisis Pulmonalis," in which the inhaler is described, and its utility emphasized, in ten cases of pulmonary phthisis treated by him in Bellevue Hospital. Dr. Rutson Maury was at that time Dr. Flint's house physician, and it is stated that I told Dr. Maury about inhaler and inhalant before he entered the hospital. Dr. Flint also states in the article referred to that he has "employed the method of inhalation here described, conjoined with other treatment, in private practice, with good results. In a case of irritative cough of several months' standing, with slight bronchitis and emphysema, but no signs of phthisis, which resisted ordinary treatment, three inhalations produced complete relief, and the cough had not reappeared at the end of four weeks" (p. 620).

Of course, in many instances, even of a common cold, something more is required to stop cough than the use of the zinc inhaler. A dose of Rochelle salts, a counter-irritant application to the chest, and spirits of mindererus internally, combined or not, with sweet spirits of nitre, will be helpful, especially where the patient has fever, and is, or should be, housed. If these simple remedies were used habitually in ordinary cases of colds, and coal tar derivatives abandoned, there might be, perhaps, fewer instances of pneumonia.

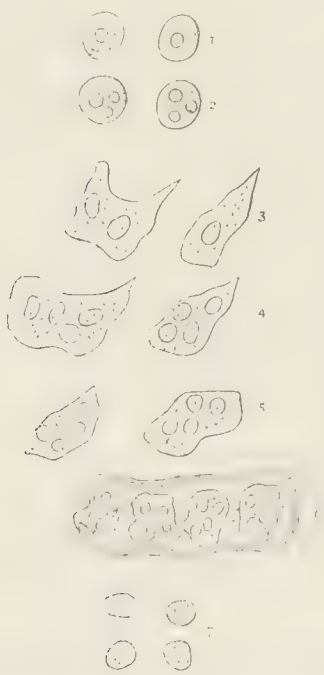
OBSERVATIONS ON THE ETIOLOGY OF CANCER.

By WILLIAM H. DIEFFENBACH, M.D.,
NEW YORK.

In spite of notable medical progress during the past decades in other directions, especially in surgery and in physical diagnosis and therapeutics, the mortality from cancer shows a progressive increase, one death in thirty being attributable to this disease, according to present statistics. Many efforts have been made, and are still being made, to clear up the mystery of cancer etiology, but the question still remains unsolved. Believing that any ray of light, even if of slight penetration, which may help illuminate this topic would be welcome, the writer desires to jot down his observations on over one hundred cases of cancer treated during the past few years at the clinics in Flower Hospital, New York, and in private practice, and draw such conclusions as seem available from accumulated data.

We are familiar with the theory of Virchow, who emphasizes local disposition due to injuries, operations, and irritations as a cause for cancer. He also speaks of hereditary transmission as a factor in this disease. Cohnheim's theory of defective embryonic development causing the formation of tumors and of misplaced epithelial cells which undergo cancerous proliferation, is taught from the rostrum as one of the plausible explanations of the etiology of this disease.

Recently Beard (Edinburgh) has promulgated a theory along similar lines. He believes that "aberrant germ-cells" are produced in what he terms the "critical period" in embryonal development, and that a tissue called trophoblast is formed from which cancer propagates. This tissue has lower vitality than normal tissue, and can be destroyed by the digestive properties of pancreatic ferments, notably trypsin. This is practically the essence of "the newly discovered cancer-cure," as described in a recent magazine article.*



Epithelia and sarcoma corpuscles (from Ziegler), 1, Renal epithelia from the convoluted tubules; 2, the same with endogenous new formations; 3, urethral epithelia; 4, the same with endogenous new formations; 5, squamous cancer epithelia; 6, cancer nest; 7, sarcoma corpuscles.

Gaylord (Buffalo) claimed three years ago to have discovered the cause of cancer in a coccidium—the *Coccidium sarcolytum*—which, when inoculated, produced similar lesions to those of the parent body from which it was derived. This discovery has been affirmed by some, denied by others, the latter claiming that the microorganism was due to incidental contamination or was a by-product of degenerative tissue change.

Doyen (Paris) has isolated the *Micrococcus neoformans*, which he claims to have found in cancer tissue, and from which he secures a serum which he employs in this disease. His methods have been investigated by the Paris Academy of Medicine, and an unfavorable report submitted on same. In the cases treated by the writer the importance of trauma as an etiological factor was again and again impressed on his mind, especially, when on close questioning, obscure or seemingly unimportant recurring irritation or trauma was elicited.

*August, 1906, McClure's.

In this connection, the following observations, noted in a large number of urological examinations, induced the writer to give this factor especial attention.

In examining the urine of pregnant women it will frequently be noted that the epithelial cells of the urinary tract, upon which pressure is exerted by the developing fetus, show what have been termed "epithelia with endogenous new formations." This same phenomenon is seen when tumors press upon the kidney or bladder, or when an hypertrophied prostate impinges upon the urethral mucous membrane. In severe inflammations of the genitourinary tract the epithelial cells found in the urine frequently have these new formations, and in certain squamous epithelia, such as from the urethra, the appearance of these formations makes the epithelium look almost identical with a carcinoma cell. These abnormal cells disappear from the urine when the period of gestation is passed, or when severe inflammatory conditions are ameliorated, showing conclusively that pressure and inflammatory stress are able to change the character of cell proliferation. This point should be borne intently in mind when considering the subsequent argument.

Let us now refer to the definition of a cell, as given in Kirke's Physiology. "A cell may be defined as a nucleated mass of protoplasm of microscopic size which possesses sufficient individuality to have a life history of its own. Each cell goes through the same cycle of changes as the whole organism, though doubtless in a much shorter time. Beginning with its origin from some preexisting cell, it grows, produces other cells, and finally dies."

What, however, occurs when the integrity of these preexisting cells is interfered with? As we have had occasion to notice in the urinary examinations, the character of the cells can be changed—changed so as to be practically identical microscopically with carcinoma cells. What occurs if through repeated trauma the trophic nerve supplying a part is interfered with and its transmission of impulses is hindered? Let us quote from Kirke's Physiology once more: "The morbid effects which division of the fifth nerve produces in the organs of special sense make it probable that in the normal state the fifth nerve exercises some special or trophic influence on the nutrition of these organs; although in part, the effect of the section of the nerve is only indirectly destructive by abolishing sensation, and therefore the natural safeguard which leads to the protection of parts from external injury. Thus, after a division, within a period varying from twenty-four hours to a week, the cornea begins to be opaque; then it grows completely white; a low destructive inflammatory process ensues in the conjunctiva, sclerotica, and interior parts of the eye, and within one or a few weeks the whole eye may be quite disorganized, and the cornea may slough or be penetrated by a large ulcer." If, as we have seen, division of a trophic nerve produces disorganization of the part supplied, what happens when these nerves, through severe single trauma or frequently repeated mild irritations or trauma, become inflamed, and peripheral and interstitial changes take place in the neurotic tissue?

May we not assume that the impulses inhibiting and controlling normal cell proliferation can be interfered with, while at the same time its nutritive supply may remain undisturbed? If this assumption is plausible (and we can see no grounds upon which to absolutely reject it), may it not be possible to produce a riotous proliferation of cells, which

slowly but surely will appear as a tumor, and eventually replace or destroy surrounding healthy tissue?

The fact that the great majority of cancer cases occur past middle life confirms these contentions. Arteriosclerosis is a common and almost inevitable change occurring in advanced life; with it coincident changes in the nerve cells take place with interference of function and conductivity. Observations of the action of the Roentgen ray show that excessive repeated dermatitis with interference with the integrity of the nerves and blood-vessels of the parts rayed is apt to develop into cancer. The death of Dr. L. A. Weigel, of Rochester, New York, is still fresh in the mind of all radiologists. This physician, an early investigator of the Roentgen ray, through constant experimentation and exposure to the ray, developed lesions on his hands and arms which were diagnosed by competent pathologists as epitheliomata. In spite of operative measures, the lesion spread and eventually destroyed the patient. The death of one of Edison's laboratory helpers and of a prominent California radiologist from excessive exposure to Roentgen rays and developing cancer of the parts exposed, abundantly confirms the case of Dr. Weigel. There are a number of radiologists who at present have small epitheliomata on their hands following chronic radiodermatitis. The excessive raying of a part with bombardment of the tissues constitutes a distinct trauma, and the cancerous changes in the cells cannot readily be explained, excepting on the theory the writer has endeavored to outline.

Epithelioma and carcinoma of the cervix and uterus proper, having old, neglected lacerations of the parts as a history, are too common to require much emphasis. Why should married women be so much more subject to cancer of the sexual organs than unmarried women, if the cause be not due to traumatic irritations of the genitalia? Medical treatment and surgical repair of such lesions cannot be too strongly urged in each and every case where such chronic irritation may exist to obviate subsequent cancer proliferation. Why should the majority of carcinomata of the stomach locate at the pylorus if this outlet were not the recipient of irritations of all sorts? Why do we so frequently note that chronic cases of cholelithiasis and cholecystitis develop into carcinoma of the gall-bladder and its adjacent organ, the liver? We have seen two cases of cancer of the pancreas complicating chronic cholelithiasis, the deduction being that the stones irritated or obstructed the pancreatic duct and set up carcinomatous change in due course. Rectal cancer can be traced to incessant irritations of these parts through persistent hemorrhoids, with accompanying irritation of the mucous membrane. The use of rough or coarse closet paper may also be a factor in the development of the lesion in this region. The statement has been frequently repeated that among aborigines cancer is unknown; this would again strengthen the array of facts recited in favor of the theory above expounded. Civilization, as at present constituted, subjects mankind to all kinds of traumatism; the nearer we get to the simple life, the less the traumatism. All trades and occupations subject people to more or less constant irritation of parts involved, and favor the irregular or riotous propagation of tissue in the injured parts.

The remarkable increase in cancer of the stomach and intestines noted during the past decade may by some be referred to the improved diagnostic ability of the attending physicians. It may, however, not be amiss to refer to one feature of civilized life which may have some bearing on this subject. The old copper vessels of our grand-sires have now generally been replaced by enameled ware for cooking purposes. May not the fact that minute particles of this gritty, irritating enamel are frequently passing through the alimentary tract be accountable for inflammatory changes in the parts? May not the constantly recurring irritation of the pylorus by these and other irritants account for the abnormal cell changes which occur in this locality with such alarming frequency?

The skin, when subject to friction or mild irritation, protects itself through the formation of Keratin; when the peripheral nerve supply becomes injured, the integrity of the skin structure becomes impaired also, and changes in cell proliferation will be noted. This will readily explain the overwhelming frequency of epithelioma of the face as compared with the protected parts of the body. The face is subject to traumata of all kinds, the prominences especially about the nose being particularly subject to such irritations. In portions of the anatomy where irritation is marked, such as the feet from the wearing of shoes, the hands from manual labor, the stratum corneum throws out a protecting layer of tissue. In the aged, when the nerve and blood supply to the skin is impaired through sclerotic changes, the frequency of keratosis senilis is noted by all observers. When the condition becomes aggravated and the trophic nerves of the parts become injured, cancerous degeneration will be invited. The frequency with which senile warts and moles degenerate into malignant tissue requires no emphasis; it is so common that prominent surgeons, notably Dr. W. W. Keen, have advocated surgical removal of these benign growths to avoid possible subsequent malignancy. The writer feels convinced that cancer is due to changes in cell proliferation from inhibitive influences such as we have attempted to explain. In order not to be misunderstood, we wish to reiterate that trauma *per se* will not, in our opinion, cause these abnormal changes designated as cancer, but that changes in the nerve and blood supply of the part must supervene such traumata before these changes are gradually evolved.

An analysis of the cases under observation during the past five years shows the following:

1. Sex; about 60 per cent. women; married folk in great majority.

2. Age; passed 50; majority 52 to 65 years.

3. General health; fairly robust; constipation present in almost all the cases; hepatic disturbances common; negative history of syphilis and tuberculosis in nearly all the cases; history of gonorrhea admitted in majority of male cases.

4. Hereditary cancer in but 10 per cent. of cases.

5. Vaccination in all cases questioned.

6. After persistent questioning, history of trauma preceding neoplastic growth in 90 per cent. of cases. The statement that 90 per cent. of the cases gave a history of trauma deserves to be dilated upon. In our judgment, if the memories of the patients had been sufficiently acute or retentive, probably all the cases may have been referred to trauma in some form. Some of these traumatic causes are very remote, and no significance is paid to many daily habits which can justly be placed under this classification.

Why do women so frequently develop neoplasms of the mammary glands and of the uterus? Why, may we add, do men so frequently develop cancer of the throat and tongue?

Trauma of the female breast is a common occur-

rence of ordinary routine home life, their protrusion and prominence rendering them subject to frequent accidental blows. Women subject to coitus trauma, especially when laceration of the cervix exists or irritating discharges are constant, may be classed as distinctly in danger of abnormal cell proliferation due to the constant irritation of the parts. Cancer of the throat and tongue are so much more common in men than in women as to be noted by all observers. This is undoubtedly due to the habit of smoking, with its entailing irritation in some cases. It can be explained on no other basis. In the cases noted a large number of neoplasms were due to irritations from poor teeth, misplaced teeth, poorly fitting plates and injuries repeatedly produced by dental operations. Two cases of round cell sarcoma can absolutely be traced to injuries caused by the instruments of dentists.

Two cases of scirrhus of the right breast were traced to the habit the women had of carrying purses inside of the corset and pinning jewelry on the inside of the garment whenever they left their homes. The constant trauma of these hard, foreign substances striking the gland innumerable times can undoubtedly be put down as a factor in the etiology of the disease.

Many patients deny trauma in cases as above, and the following few cases will serve to emphasize this point:

Mr. F., æt. 60. Scirrhus of right breast. Patient denied trauma, but gave a history of being employed in carrying hides of morocco leather on his right shoulder, the flaps of the hides striking the breast constantly while he was walking from the stock room to the shipping room. This mild, constantly-repeated trauma was endured during a business career of thirty-five years, so that the breast may have been struck 100,000 times and the tumor produced through changed cell-proliferation in course of time.

Mrs. B., æt. 57. Scirrhus of left breast, located principally in the outer aspect of the breast, and most marked in the axillary line. Patient denied trauma, but on inquiry regarding habits it was found that for many years an adopted daughter has slept with patient, and on going to sleep had nestled her little head against the left side of the patient, the left arm of the foster-mother holding the child close. Here there was occasion for numerous traumatisms from the child's head, and the fact that the tumor located in the exact spot indicated by both of the resting place of the head corroborates this assumption. One case was noted where a single blow from a toy hammer in the hands of a child produced carcinoma of the breast within three months. Another history recites an accident of a fireman, who fell from a roof while in the performance of his duty, striking on the side of his body. A small swelling in his right supraclavicular region persisted after the other injuries had subsided. This was excised, examined and found to be a mixed cell sarcoma. The growth promptly recurred, involved neighboring tissues, and ultimately caused exitus lethalis.

Another case of sarcoma of the testicle was, after much questioning, traced to a poorly fitting bicycle saddle, and frequent trauma therefrom. These cases can be multiplied from the records, and innumerable traumata divulged which the patients themselves have forgotten, or paid no attention to at the time. To sum up our conclusions, we desire to make the following unqualified statement:

Neoplasms are due to interference with normal cell reproduction induced through trauma, pressure, severe inflammations, or constant irritations—these factors act upon the trophic nerves supplying the parts affected, and prevent, either through pressure, inhibition, or inflammatory changes in the nerves themselves, proper afferent and efferent impulses to the cells supplied by these nerves. When the trophic nerve is severed degenerative change in the parts served by the respective nerve are noted; when the trophic nerve is only partly destroyed or diseased, or inhibited, cell control is interfered with, and riotous, abnormal cell growth is invited.

Careful observation regarding infectiousness of cancer of bacterial or parasitic origin have in all the cases noted been of a negative character, and the long, fruitless search for the specific germ finds no encouragement at our hands.

If these statements prove correct, it behooves us as guardians of the public health to warn against neglecting traumatism of all kinds; to warn against certain habits and occupations which induce constant irritation, and to insist that when trauma occurs or exists proper medical attention be given without delay. The drop of water may hollow out a rock; persistent trauma or irritation, even if unnoticed, may cause the most profound tissue changes.

Fifty-sixth Street and Broadway.

THE IMPORTANCE OF THE EARLY DIAGNOSIS AND TREATMENT OF EPILEPTIC SYMPTOMS.

By FRANK M. STITES, M.D.,

HOPKINSVILLE, KY

We are sometimes inclined to magnify unduly that phase of a subject to which we have given special thought or attention, but I believe that in considering a disease such as epilepsy, in which the intractability to remedial measures increases so rapidly with its duration, all should be agreed that an early diagnosis is essential to successful treatment. It is not strange that physicians are loath to pronounce the disease epilepsy, nor that the family should hesitate to accept such a diagnosis as correct, for up to the present time no name carries with it more terror and no sentence to suffering is more hopeless. Generally the disease has become fixed on the individual before either the physician or the family are willing to accept the correct diagnosis, and before the proper measures are instituted for relief. This should not be so, and I believe that in most cases a diagnosis of epilepsy is possible very early, and in some instances with reasonable probability after the first two or three seizures. Oppenheim is perhaps correct, however, in saying that the diagnosis of epilepsy should never be made with the first convulsion.

The most serious obstacle in the way of an early diagnosis of epilepsy at the present time is a lack of a definite knowledge of the pathology of the disease. Perhaps it may be shown, as investigation clears up the true pathological conditions, that there are several diseases which are now classed as epilepsy. As it is, we are practically dependent on the objective symptoms, which in most cases must be described by the family of the patient—often too ignorant to observe just what is of most importance for the physician to know. Another serious obstacle is the fact that

*Read before Kentucky State Medical Association, Owensboro, Ky., October 12, 1906.

convulsive seizures in every way identical with epilepsy, so far as the individual attacks are concerned, are commonly associated with a number of diseases, and yet are permanently relieved with the removal of the exciting cause. In spite of these and other difficulties in the way of a prompt and positive diagnosis, the extreme gravity of the disease when it has become permanently fixed on the patient should encourage the profession to recognize the symptoms at the earliest possible stage in its development. There is no other disease except insanity which causes more mental anguish to the patient and his family. The constant menace of the seizures; the fearful appearance of the convulsion, and the almost certain effect of the disease in destroying the mind, cannot be adequately described. Though even in advanced cases cures are sometimes possible, it is well recognized that the chronic epileptic is about the most unsatisfactory patient that can apply for treatment, and consequently many of them are allowed to become a prey to quacks and patent nostrums, and these human parasites greedily seek them with glowing advertisements and long lists of testimonials of permanent cures effected in a few weeks or months. Spratling, in his work on epilepsy, says: "Recent cases are twice as likely to respond to treatment as chronic ones." And again: "It seems fair, on the whole, to say that even with an almost entirely chronic class, we may expect a cure of about five per cent. If all could come under treatment early enough this percentage could be doubled or trebled." This statement is clearly upheld by statistics, and it is probably equally true that if we could begin proper treatment with the first seizure the percentage of cures would be many times greater.

The question naturally arises, is it ever possible to say in any case that the first seizure is epileptic, or is it necessary to wait for successive returns to fix the habit on the sufferer before a diagnosis can be made or the proper treatment instituted? This question may be answered by the pathologist before many years, but as yet it is not often, if ever, safe to pronounce a patient epileptic with the first seizure. The long treatment and the rigid care which should follow the diagnosis of epilepsy should not be inflicted on anyone without good reason for believing it necessary. In some cases, however, the presumption may be very strong with the first manifestation of the symptoms, and a single return, when all the facts have been carefully observed, should enable the physician to give a positive opinion.

Among the several features that must be taken into consideration in making an early diagnosis of this disease, are two of special importance. First, that it is essentially a disease of early life, and next that an hereditary predisposition is found in a majority of the cases. As the study of the disease progresses and statistics accumulate it is probable that these two facts will be more strongly emphasized. Even though a strong hereditary tendency may not be sufficient to produce the disease of itself without the exciting cause, yet more than half of the recorded cases show hereditary susceptibility to have been present in greater or less degree. An alarming number are found to be due to direct heredity-epilepsy in one or both parents. This, strengthened by the fact that insanity in the offspring of epileptic marriages is a common occurrence, should by all means lead to the enactment of a stringent law forbidding the marriage of epileptics. Such a law would greatly diminish both epilepsy and insanity in the succeeding generation.

Alcoholism, syphilis, tuberculosis, insanity, and the neuroses are responsible for their share of epileptics, and until the people can be educated to require at least as clean a family history for the marriage contract as is now required to obtain a contract for life insurance, we may reasonably expect a steady increase in the prevalence of this disease. The history of any of these diseases in the ancestry of a patient should add great weight to the diagnosis of epilepsy in doubtful cases, and should assist in arriving at this conclusion at an early stage in the disease.

The great majority of all cases of epilepsy begin in early life, and it is rare for it to develop after the second decade. Strange to say, convulsions in nervous children and those having an hereditary susceptibility to nervous diseases, have been regarded as of less consequence than those occurring in more normal individuals. So high an authority as Holt says, "Except when convulsions mark the beginning of epilepsy they are much less serious than they are generally regarded by the laity. In a highly nervous or susceptible child a convulsion may often mean no more than an attack of severe migraine in an older person." The importance of an inherited susceptibility is well illustrated by Spratling in the work already quoted. He says, "Given an individual in whom epilepsy may be induced under the influence of some irritation, of which the climax—*i. e.* the point at which it causes the seizure to appear—is represented by 100. If there are already present sixty of these points from, we will say, a predisposition due to heredity, there will remain but forty to be supplied by some exciting cause to bring the disease to light." It is, therefore, a serious mistake to regard convulsions as of minor importance in nervous or susceptible individuals.

Take the two facts just mentioned, that epilepsy is generally hereditary, and is usually developed in early life, and the conclusion is forced that convulsions occurring in early life in one already made susceptible by heredity should be regarded as strongly indicating the probable development of epilepsy. Regardless even of these things, convulsions in infancy and childhood should always be regarded as the possible beginning of epilepsy. Coutts gives the after-history of eighty-five cases studied by him. Forty of these suffered from pronounced neuroses in later life, and of these, twenty-five, or about 30 per cent. of the whole number, developed epilepsy, thus showing a clear connection between infantile convulsions and true epilepsy in a large per cent. of his cases. Other statistics confirm this. Even in a child of healthy parentage, a convulsion from any cause may be complicated by hemorrhage into the brain cortex that will finally result in epilepsy by the continued irritation which is left.

The presence of the mental or physical stigmata of degeneration should add to the gravity of the prognosis in convulsive seizures and should assist in determining the diagnosis of epilepsy at a much earlier stage of development. The signs of degeneration should be looked for in all cases of nervous diseases, and especially when epilepsy is suspected, because they may assist in deter-

mining the existence of this disease. If the only epileptics were those who suffered from the beginning with grand mal attacks the question of diagnosis would be greatly simplified. The purely psychic and the milder forms of petit mal seizures render the diagnosis at times very uncertain.

It would hardly be proper to say that epilepsy has a prodromal period in its development, but the first seizures may be so mild and insignificant in their manifestations as to escape notice for many months, or even years. The physician may not even be consulted, and if he is, the description of the attacks is often misleading and entirely inadequate for the purposes of diagnosis. I have seen a case of purely psychic epilepsy that was treated for years as syncope, and another, beginning as petit mal, in which the aura was felt as a pain in the right arm and the loss of consciousness was not complete, was treated for months as rheumatism. A reputable physician of my acquaintance treated a case of grand mal convulsions for a considerable length of time for another disease because the parents could not give an intelligent account of the seizures, and because the symptoms that were present in the intervals were of a deceptive nature. In every doubtful case with obscure nervous symptoms where there is the possibility of epilepsy, the first step in arriving at a diagnosis should be to place the patient under the constant care of a trained attendant, intelligent enough to record all the symptoms of the disease and give the attending physician an accurate picture of the condition of the patient; for it is very rare for the general practitioner to be able to see the actual seizure, and he must depend upon the description given him, and ordinary observers are incompetent to describe the obscure symptoms of this disease.

There should be no difficulty in recognizing grand mal seizures or petit mal where the loss of consciousness is complete, but at first the attacks may be purely psychic, and the loss of consciousness and convulsions in the seizures of petit mal may be so slight and transient as to pass entirely unnoticed. When a severe convulsion brings the true nature of the disease to light the habit has become firmly fixed and the possibility of cure greatly diminished by the duration of the attacks.

In the beginning of a Jacksonian epilepsy the convulsion may be confined to a single group of muscles, and there may be no impairment of consciousness at all. It is well known that the seizures may for a long time be nocturnal, and occur only during the hours in which the patient is asleep, and if he sleeps alone the only sign will be nocturnal incontinence of urine or feces, with headache and malaise the next morning, and possibly a sore tongue. In older children nocturnal incontinence should create the suspicion of epilepsy, and the other symptoms should be carefully looked for.

Physicians should be extremely careful in pronouncing any obscure mental or nervous phenomena as of no consequence, and in nervous or susceptible individuals where the symptoms occur periodically with comparatively normal intervals, the possibility of epilepsy should receive due consideration. It is not at all uncommon in cases of this disease which are supposed to be of recent development, to get a history of peculiar "spells" extending over a long period, and it is more than probable that these "spells" were the objectively milder manifestations of epilepsy. Unnatural mental or motor activity, temporary aphasia or amnesia, transient attacks resembling syncope, any of these symptoms occurring periodically with normal intervals may properly receive attention as being possibly connected with obscure attacks of epilepsy. In the case of a boy, grand mal attacks developed in his fifth year and continued for five weeks with intervals of a few hours or a few days between the seizures. For several weeks before the convulsions, however, there was a history of periods of decided motor activity and mental excitement that were attributed by his parents to bad temper, and under this impression he was punished for these "spells" until the severe convulsions revealed the true nature of the trouble. In another boy, age seven, petit mal attacks were not recognized for several months because loss of consciousness was not complete, and the intense mental excitement obscured the nature of the attacks. Physical restraint and punishment were both resorted to in this case before the true character of the disease was recognized.

Many chronic epileptics can be traced back and their seizures found to have begun as convulsions associated with scarlet fever, whooping cough, and other diseases of childhood. It is not possible to say that these convulsions really marked the beginning of the epilepsy, in the sense that the first convulsion was epileptic, for the first convulsion may have produced a hemorrhage in the brain cortex that was the real cause of the succeeding seizures.

The frequent connection between epilepsy and the convulsions associated with the common diseases of infancy and childhood should suggest a more careful study of this symptom, and should render the prognosis as to permanent relief more guarded and the attention to the after-treatment more thorough. The profession is not free from criticism in this connection. While the family can generally be assured that the immediate danger to life in ordinary cases is small, yet they should always receive instruction as to the possible return of the seizures, and the meaning of the symptoms explained, and at the same time they should be cautioned to avoid all possible sources of irritation.

To summarize the subject:—(1) A diagnosis of epilesy at the earliest possible stage of its development is essential to successful treatment.

(2) Convulsions from any cause and at any age are not to be regarded as of slight significance, but the possibility of the development of epilepsy in every case must receive careful consideration.

(3) Recurring convulsions in the young, associated with hereditary susceptibility to nervous diseases, should invariably be regarded as probably epileptic in their nature. The more insignificant the exciting cause the stronger the indication of this disease should be regarded. It should be remembered, at the same time, that each return of the seizure renders permanent cure more doubtful.

(4) In all cases in which obscure mental or nervous symptoms tend to recur periodically with normal intervals the possibility or probability of epilepsy in the form of psychic, Jacksonian, or petit mal seizures should be considered, and careful study be given to the symptoms; and when possible, the case should be placed under the care of an intelligent attendant until the diagnosis is

positive. No unnecessary delay is permissible in these cases, for they are generally regarded as less amenable to treatment than the grand mal seizures, and the fact that most often the diagnosis is delayed in these types of the disease may account for the failure in results.

(5) Though care should be exercised in doubtful cases it is better to give the patient the benefit of the doubt and institute treatment early, even when a positive diagnosis of epilepsy is not possible, than to allow the condition to become chronic and perhaps hopeless. The general care which should be given to a patient supposed to be epileptic would, in fact, benefit any obscure nervous disease, whether convulsive or not in its nature. A positive and early diagnosis is important, but the early treatment is of far greater importance, and proper treatment should be begun as soon as the diagnosis is reasonably certain and should be persistently carried out until the result is assured.

LATE RESULTS OF THE *X*-RAY TREATMENT OF CUTANEOUS EPITHELIOMA.*

By CHARLES MALLORY WILLIAMS, M.D.,

NEW YORK.

THE cases upon which this report is founded all occurred in the private practice of Dr. L. Duncan Bulkley, to whom I am indebted for the privilege of recording them. They form the basis of an article which appeared in the *American Journal of the Medical Sciences* in March, 1905, and in view of the lapse of time since the preparation of that paper, now nearly two years, it may be interesting to follow the later history of the patients, who, up to that time, had remained free from any recurrence.

The original article concerned eighteen patients suffering from epithelioma of the face. They fell naturally into three classes. The first class consisted of two cases of epithelioma of the lower lip; the second, three cases in which the growth was situated deep in the cutis, and was of considerably greater extent than the small area of ulceration over it; while the third class comprised thirteen cases in which the growth was very superficial.

The different classes responded very differentlv to treatment. Of the two cases of epithelioma of the lower lip, one patient showed no improvement whatever after a month of treatment, and had the tumor excised, and six months later died after an operation for recurrence. The second patient in this class improved, and after December, 1903, showed no sign of the disease, the lip appearing normal, "except a very slight shrinkage on one side," as he wrote to me August 29, 1906. Since 1903 the only *x*-ray treatment was a few exposures in August, 1904, given with the idea of preventing a recurrence, as there was then neither hardness nor ulceration. This case is the more noteworthy because a tumor in this region is usually especially resistant to *x*-ray treatment.

The three cases in class two, those in which the hardness was deep, and out of proportion to the ulceration, all did badly. One of them, it is true, was very irregular in his attendance, and did not give the method a fair trial; the other two were faithful, but, in spite of repeated and prolonged exposures, carried to the point of producing dusky redness and peeling, with varied conditions of tube vacuum, the benefit was very limited. The small ulcer in each case healed readily, but the hard mass beneath seemed little, if at all affected.

The results in the third class were much more encouraging. One, a man of eighty-six years, died from the rupture of an artery after about two months of treatment, when the growth had nearly disappeared, and two ceased treatment, although they were progressing nicely, and have since escaped from observation. The remaining ten cases are those to which I wish particularly to call your attention this evening. In all, the lesion was on the face, above the mouth, and in all it was of the same general type, the characteristic mark of which is its superficiality. The induration seems to be in the skin itself, and quite near the surface; never deep as in class two. The borders are generally narrow, slightly elevated, firm, grayish white, and composed either of separate pearly nodules or of such nodules run together to form a ring, or part of a ring. The base is sometimes fairly deeply excavated, but usually it is only a little below the surface of the surrounding skin. It is sometimes a bright red, and moist from exuded serum, but the exudation is never very great, and often dries to a scab, which falls from time to time, or may be pulled off, leaving a moist, easily-bleeding surface, or the base may be only delicate pink scar tissue. This type of epithelioma is always comparatively benign, as is shown, indeed, by the long duration of the disease in some of the patients in this series—twelve and thirteen years, respectively, in two of the cases.

Of the ten cases, two have died. One of these (No. 3) had an ulcer about one-eighth by one-quarter of an inch, near the free border of the left lower eyelid. This healed after about two months of treatment, only to be followed about a month later by a pearly nodule, a little external to the scar. This disappeared after about six weeks of treatment, and there was never any recurrence. His general health was not good, however, and he died, aged sixty-one years, in September, 1905, one year and eight months after the last treatment, having been in bed four months with "rheumatism, neuralgia, and a complication of diseases," as his wife wrote me. The second death (No. 6) was that of a woman of seventy-eight years, who had had an epithelioma on the left cheek, which healed readily after a month's treatment. She was a chronic invalid, however, suffering greatly every winter from bronchitis, and in January, 1906, two years and three months after the last treatment, she died. Her son, a very intelligent man, was with her constantly, and wrote to me about a month before her death that she was losing ground steadily, but that there was no trace of a local return, and no symptom of internal cancer.

Another case (No. 5) had several scattered, wasty spots on the cheeks and nose, one of which had gradually developed into an epitheliomatous ulcer, and was therefore given much more intense treatment than any of the others. This spot, apparently, was cured, and was replaced by a smooth scar, which was still perfect three years and nine months later. The patient became very irregular in his attendance, however, and it is perhaps due to this that, in spite of repeated applications of the *x*-ray, the other spots have never healed. In fact, one, which was only warty at first, became much worse, and ulcerated, but now, he writes me, is improving again under more regular treatment. As far as the spot first treated is concerned, the result is excellent, but on account of this development of an ulcer at

*Read before the Section on Dermatology, New York Academy of Medicine, October 2, 1906.

another point he cannot be ranked better than improved.

Two cases recurred *in situ*, one seven months, the other two years, after the last treatment. It is only fair to add, however, that both of these patients ceased treatment before the physician was satisfied with the result. In one case (No. 9) the lesion showed no change whatever, after seven exposures in the course of two weeks, except an increase in redness, yet it disappeared entirely without further treatment during the next six weeks, and only reappeared two years later. It is still of the same mild type as before, for the patient writes me that "there is still a little redness on the spot treated, sometimes threatening. Just below that there is still a little point now" about an eighth of an inch in diameter "almost double the size" it was a year ago. "The crust comes off frequently, and the spot is then scarcely noticeable." The recurrence in the second patient (No. 8) also seems to be very small and of slow growth, for I have had letters from him once or twice a year for the last three years, and his really careful descriptions of the appearance of his disease hardly vary from letter to letter. The scar left by previous treatments is about an inch square, and in one corner of this is an ulcer, ranging from one-eighth to three-sixteenths of an inch, now better, now worse. The rest of the scar is healthy.

The remaining five patients were all well when last heard from, less than two months ago, at intervals ranging from two years and three months to three years and six months after the last treatment, and all declare that they can find no trace of their old trouble, save a smooth, healthy scar. Unfortunately, I have not been able to examine them myself, and have to trust to letters, but the natural dread of cancer makes these people very careful observers, and I have no reason to doubt their honesty. The good results in some of them have far surpassed all expectations, for one patient had but a single exposure, yet was free from recurrence two years and six months later; while another, whose attendance was so irregular that I despaired of permanent cure, has now been free from his disease for two years and three months. These men are now seventy-eight and eighty years old, respectively, and this raises an important point in the choice of a treatment for cutaneous epithelioma. Many of the patients are of advanced age, at a period when the danger of an operation, or of general anesthesia even, is a serious matter, and at a time, too, when their natural expectation of life is so short that they are likely to die of some other disease before the tumor causes them any serious inconvenience, if its growth can be held in check for a few years. Nevertheless, the freedom from recurrence, after a prolonged period of observation is the most important evidence of the value of any method of treatment, and it is the chief purpose of this paper to add a little to the scanty available data bearing on this subject. The lapse of time, even in the best of the cases, is too short to give absolute assurance of cure, but nevertheless it is long enough to establish a strong presumption of permanence, which is strengthened with every passing month, and which is favored also by the fact that the last recurrence, even in the insufficiently treated cases, was noted a year ago, since which time there has been no defection, save by death from independent causes. The list is too short, also, to serve as a basis for the calculation of the percentages of cures and failures. It is but a single contribution, among the many that must be collated, before we can reach a just estimate of the therapeutic worth of this strange force.

No	Age	Site	Last Treatment	Last Report	Result
1	41	Temple	Mar. 27, 1903	Sept. 10, 1906	No recurrence after 3 yrs., 5½ mos.
2	78	Front of ear.	May, 1904	Aug. 19, 1906	No recurrence after 2 yrs., 3 mos.
3	80	Lower eyelid	Jan. 28, 1904	Sept., 1905	Died. No recurrence after 1 yr., 8 mos.
4	76	Cheek	Mar. 20, 1904	Sept. 12, 1906	No recurrence after 2 yrs., 6 mos.
5	61	Cheek		Aug. 22, 1906	No recurrence after 3 yrs., 0 mos. in one spot; fresh outbreak at another point soon after healing at the first.
6	76	Cheek	Oct. 20, 1903	Jan. 10, 1906	Died. No recurrence after 2 yrs., 3 mos.
7	40	Cheek	Jan. 2, 1903	Aug. 29, 1906	Recurrence after 7 mos., in corner of scar, now progressing very slowly.
8	81	Nasolabial fold	Oct. 19, 1903	Aug. 21, 1906	No recurrence after 2 yrs., 10 mos.
9	75	Nose	Sept. 16, 1903	Sept. 8, 1906	Recurrence after 2 yrs., just below scar; progressing very slowly.
10	64	Skin of upper lip	July 15, 1903	Aug. 17, 1906	No recurrence after 3 yrs., 1 mo.
11	41	Lower lip	Aug. 17, 1904	Aug. 29, 1906	No recurrence after 2 yrs.

SOME ETIOLOGICAL FACTORS IN BONE TUBERCULOSIS IN CHILDREN.*

By CHARLTON WALLACE, M.D.,

NEW YORK.

In accordance with the resolution adopted by your board last fall, I wish to submit the following report concerning the investigation of some of the causes of bone tuberculosis in children.

It has not been satisfactorily proven why the tubercle bacilli, the microorganic agency, select the bone instead of the lungs in these cases; but authorities seem united in the theory that the bone is involved secondarily to the infection of some gland, where the disease is quiescent; this subsequently breaks down, and the bacilli circulate in the blood and are deposited in the new-forming bone, where, the blood supply being most profuse, a fertile soil for growth is furnished. The exciting cause, whether injury, acute disease, or weakened general condition, irritates the bacilli into activity. Destruction results because the tender developing tissue has not the strength to resist the inroads.

In considering the etiology we will exclude congenital affliction, for so far medical science has reported but twenty-three (23) cases in which tuberculosis existed at birth, and none of these was of the osteal variety. But a predisposition may be inherited, and by a predisposition we mean a constitutional defect and unsoundness of the original construction of some organ or tissue at birth, which makes one more susceptible to the contraction of the disease when exposed. This factor we recognize, but do not believe that it plays so prominent a part as environment in creating the susceptibility to the disease.

Lack of proper nourishment, poor ventilation, personal uncleanliness, and overcrowding so weaken the system that it furnishes an excellent bed for the growth of the bacillus of tuberculosis, and when acute disease or injury further debilitates, exposure only is necessary, and the disease is contracted. These facts are generally known.

*Report to the Board of Directors of the Crippled Children's Driving Fund of New York.

During the past year we of the Crippled Children's Driving Fund of New York City, with the aid of the records at the Ruptured and Crippled and New York Orthopedic Hospitals, and the Department of Health, have been enabled to make some investigations concerning the true influence of these agencies in causing this disease. We have secured only two hundred and forty-three complete records, because families of patients objected to giving the desired information. Our choice of cases has been limited to those dating back three years, since the present full records of the Department of Health of New York City have been in existence only during that time. Also the patients change their addresses so often that it is hard to locate them after any great lapse of time.

The average daily expenditure per capita for all expenses, exclusive of rent, we found to be, for Class I. fourteen and one-half cents, and for Class II. twenty-five and one-tenth cents. (See Table.) With this small sum for fuel, light, clothing, and food, how is it possible to secure enough nourishment to keep the tone of the tissues and organs in proper condition to resist disease when exposed, or to cure it when contracted?

The ventilation was in general inadequate. Three reported windows open wide; one hundred and forty-two, open one to two inches, and ninety-eight windows kept closed. The rooms were, as a rule, dark, and not exposed to sunlight, accommodating about two people to a room.

The most significant facts of all, the statistics show that 110 of these cases had resided within infected dwellings where pulmonary patients had lived. Eighty-six had been exposed within the family, through either a member of their own immediate family or a boarder, and had come in personal contact with these. This gives us forty-five per cent. who lived in infected dwellings and thirty-five per cent. who came in direct contact with those suffering from pulmonary tuberculosis. Thus, we have a combined percentage of eighty, but sixteen per cent. of these were exposed in both ways, which gives us finally sixty-four per cent. of the two hundred and forty-three cases with a history of exposure.

The bathing was insufficient. Eighty-eight were bathed twice a week, sixty-nine weekly, and eighty-six irregularly, and not oftener than once in two weeks.

As the Department of Health disinfects after tuberculosis only in the event of death or removal of the patient, their records show that only seventeen of the one hundred and ten places have been disinfected.

Cornet of Berlin reported in 1890 that in twenty-eight homes visited in which pulmonary patients were dwelling, the dust of sixty-seven per cent. contained inoculable tuberculous bacilli, and Harold Coates of Manchester, England, in 1901 found that of thirty-one homes in which pulmonary cases resided, sixty-one per cent. contained dust laden with the tuberculous microorganism.

It is our belief that two strong factors are instrumental in the acquiring of bone tuberculosis, viz., inherited tendency and unsanitary and otherwise unfavorable environment. The first we cannot remove; the second we can remove, and thus render latent the effect of the former.

In closing, let me add a plea for a better education of sufferers from tuberculosis that they may guard against infecting the little ones, for thorough disinfection of rooms occupied by pulmonary cases, for the removal of those children afflicted with bone tuberculosis to the country or seaside. Use your influence to awaken the public to the need of seaside and country hospitals for the little sufferers of this saddest and most painful form of the white plague. Save the children from the folly and ignorance of their elders whenever it is within your power.

TABLE SHOWING EARNING CAPACITY AND EXPENSES OF FAMILIES IN WHICH BONE TUBERCULOSIS OCCURRED, TOGETHER WITH PERSONAL STATISTICS.

The cases are [illegible] according to the [illegible] capacity of the entire family below or above $45.00 per month.

Number of cases ... 243

Class I. [illegible]

Total Earnings, $3,404.50 per month for 566 persons.

[illegible]

.145 per capita per day for food, clothing, etc.

Class II. [illegible]

Total Earnings, $8,450.50 per month for 906 persons.

SARCOMA OF THE NASAL FOSSA.

By RICHARD H. JOHNSTON, M.D.,

BALTIMORE, MD.

Some years ago I saw a case of sarcoma of the nasal septum with involvement of the cervical and axillary glands. A detailed description of the case appeared in the *Laryngoscope*. Recently I have seen another such case with a different point of origin which may prove of interest.

Mrs. P. H. M., sixty-five years old, consulted me March 8 of the present year for right nasal obstruction and neuralgic pains in the same side of the face. She was positive in the statement that her first symptoms of "cold in the head" and neuralgia had come on three weeks before. There was a decided, hard, nonpainful prominence of the nose externally, which she said had been present for years. On looking into the nose a grayish white mass, hard to the touch, could be seen above. Below, on a level with the inferior turbinate body, was a pink growth, which bled easily. There was no doubt as to the malignancy of the tumor. The septum was pushed over to the opposite side, making respiration through that nostril impossible. The family of the patient was informed of the seriousness of the case and the improbability of removing all of the growth by an external operation. An operation was insisted upon, however.

On the following Tuesday, March 14, the nose was opened by an incision in the nasolabial fold and the soft tissues turned to the opposite side. The nasal bone was removed with cutting forceps and a free view obtained. The hard, rounded mass revealed itself as a bony cyst of the middle turbinate which had no connection with the tumor proper. Hemorrhage was free. The fossa was filled with large masses of the growth which was attached to the middle and inferior turbinates, the floor of the nose, and the walls of the antrum. The origin seemed to be from the antrum with a breaking through into the nose and an infiltration of its structures. The septum was not involved. It was seen at once that there was no possibility of removing the entire mass. With the curette an effort was made to clear a passage through the

nostril to make the patient more comfortable. This was only partially successful—a large mass was found extending into the nasopharynx, all of which could not be removed. The nostril was packed and the patient put to bed. She recovered from the operation, but the tumor recurred promptly. In a short time the external swelling again appeared and the growth was seen at the anterior naris. The operation seemed to stimulate the growth of the tumor and in a few weeks a large, red, vascular mass was hanging out of the nostril. A second operation was declined by the patient. She sank gradually, and died May 16, of exhaustion. The patient was made more comfortable by the operation, in that the severe pain which she suffered before was relieved. The examination of sections of the growth showed a very malignant, mixed cell sarcoma. Blood-vessels were numerous, and no connective tissue could be made out. Such cases show how helpless we are against malignant growths about the head, and especially about the nose. Unless we can see such patients in the beginning and make an early diagnosis, we may be sure that any operation will be followed by early recurrence. Unfortunately, patients do not consult rhinologists until it is practically impossible to remove all the diseased tissue. Experience teaches that unless we are reasonably sure of removing the entire growth, it is, perhaps, better not to operate, since what is left increases rapidly in size.

919 N. Charles Street.

Physiological Albuminuria.—G. Saccone has made a study of the frequency of albuminuria among the men of the Italian Navy, who are carefuly examined before they enter the service, and are not accepted until it has been proven that they are perfectly healthy. In the service they are subjected to severe strain from the nature of the service, and the necessary exposure to cold and heat with severe exertion. At the same time they live hygienically, and are constantly in the open air while the diet is carefully supervised. Albuminuria occurring in these men may fairly be considered as physiological and not pathological. The author made systematic urinary examinations of the urine of 400 men, part of them sailors, others firemen. Some were at sea, while others were working on land. As a result of these examinations he tells us that he found albuminuria in seventy-six to eighty-five per cent. of these men. It was essentially transitory, and was always in small amount, from .04 to .20 milligrams per thousand. He concludes that there is good evidence of the existence of physiological albuminuria in robust men when undergoing fatigue. Those men employed on the sea showed more frequent albuminuria than those employed on shore, and it was larger in amount. The life at sea has evidently an influence on the production of physiological albuminuria.—*Annali di Medicina Navale.*

The Question of the Mode of Infection in Malta Fever.—Edward H. Ross states that up to the present time the *Micrococcus melitensis* has been found constantly in the blood of patients suffering with Malta fever, even in such a small quantity as five milligrams of the peripheral blood, and it has been found to be excreted intermittently in the urine; consequently, as in other analogous diseases, the possible modes of infection in Malta fever are: (a) By direct contact with Malta fever patients. (b) By the clothing which has been worn by Malta fever patients. (c) By urine-infected dust. (d) By urine-infected water or food. (e) By biting insects. (f) By transmission in some way from some intermediate host. In order to test the first mode of infection, a man suffering from Malta fever contracted in a Malta hospital was nursed in the ordinary sick-berth of a warship for a month by some non-immunes, who were in daily contact with the ship's company, but none of them contracted Malta fever. This was repeated in another ship with negative results. The ordinary experiments with clothing which had been worn by the patients were tried. The results in these cases were negative. Urine, obtained from a Malta fever patient, mixed with some dust, was sniffed up the nostrils by two non-immunes. The experiment was repeated several times, but none of the men contracted the disease. Urine from a fever patient was mixed with water, which was drunk by six non-immunes, none of whom contracted Malta fever. Four non-immunes drank goat's milk which contained diluted urine in which the micrococcus was present. These men all remained well. The opinion is held that the common and specific mode of infection in Malta fever is by biting insects. Many kinds of biting insects have been experimented with, but, owing to the fact that the investigators were living on board ship, they often had the greatest difficulty in keeping the insects alive and making them bite regularly. Apparently the right insect has not yet been hit upon, for none of those conducting the experiments contracted the disease. Zammit found goats to be susceptible to Malta fever. The *Micrococcus melitensis* was found in the milk of these animals. Later it was discovered that cows also were susceptible to Malta fever. Non-immunes who drank goat's milk in which living cultures of the micrococcus were put remained well. Unfortunately, naturally infected milk was not to be obtained. The blood of thirty-eight horses in Malta has been examined and four of these animals reacted to Malta fever. The writer concludes that, as horses do not eat offal or drink goat's milk, the micrococcus of Malta fever in all probability is not conveyed by the drinking of milk or the eating of offal, but by an insect, as yet undiscovered, which transmits it from person to person, goat to goat, cow to cow, and horse to horse, and possibly from one of these animals to the others.—*The Journal of Tropical Medicine.*

The Surgical Treatment of Tuberculous Glands in the Mesentery.—Edred M. Corner cites cases which show that the removal of tuberculous glands from the mesentery of the intestine can be followed by complete success. The writer also shows the danger of delay, describing one patient who was submitted to operation too late, as the glands had led to a general infection of the body—miliary tuberculosis. Tuberculosis of the mesenteric glands most often in adults affects the lymphatic glands which drain the appendix or the ileocecal region. Suppuration is very uncommon in the mesenteric glands. One of the patients described in this article was a boy six years old. Palpation revealed a well-defined, somewhat rounded mass about the size of a cricket ball in the region of the cecum. The swelling was movable. There was some tenderness on palpation. Small nodules were felt on its anterior surface. The liver extended one finger's breadth below the costal margin; the spleen was not enlarged. The other systems were normal. At operation the peritoneal cavity was opened. Incision was made into the abscess cavity, the walls of which were very thick. The greater part of the sac was cut away and the remainder was curetted. The cavity was closed with two rows of silk sutures after being thoroughly irrigated with salt solution. The abdominal wound was closed in layers. The wound healed by first intention. It is now about two years and three months since the operation. The patient has grown strong, has put on flesh, and has maintained the improvement in every way. The writer believes that there is a stage in cases of abdominal tuberculosis which is amenable to surgical treatment alone.—*Treatment.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 8, 1906.

THE OPEN-AIR TREATMENT IN HOSPITALS.

IT has long been recognized that a plentiful supply of fresh air, particularly if this can be obtained in the open, is of signal value in the treatment of a great variety of diseased conditions, both medical and surgical. One of the most familiar examples of this is in the treatment of tuberculous affections in which an abundance of fresh air is universally accepted as the *sine qua non* of a successful outcome. Not only in the more medical aspects of the condition is this admitted, but also in those instances which were formerly believed to be curable by extensive operative interference only, where a continuous outdoor life in a suitable climate has resulted in a complete and permanent recovery. It is not always possible, however, to provide the climatic change desired, and recourse must be had to procedures entailing less inconvenience and expense. In cities the house roof naturally suggests itself as the most desirable substitute by which the necessary modicum of fresh air may be provided for a patient. Northrup of this city has proposed the utilization of the roofs not only as an essential in the treatment of certain diseases, but also as a means of providing a healthful playground for children.

Some of the larger hospitals of New York City have in recent years also made arrangements to send their convalescent patients to the roofs of the buildings, and at the New York Lying-in Hospital special provisions were made for this purpose in the planning of the structure. J. W. Markoe calls attention, in an article in the *Bulletin of the Lying-in Hospital*, September, 1906, to the good results obtained by a sojourn on the roof by the pale, anemic women from the tenements waiting to be confined and also by those suffering from some of the complications of pregnancy. By the aid of a regular ward organization patients can be kept on the open roof or in an adjoining enclosed solarium both day and night, if necessary, and in this way given the benefit of continuous exposure to the air. The writer cites a number of specific cases in which the patients' general and local condition improved under this régime. A particularly good effect was evident in those women suffering from the effects of the toxemia of pregnancy and also in the complicated postpartum septic cases in which the almost exhausted vitality of the women offers but little resistance to the progress of the infection.

Dr. Markoe's article constitutes an effective plea for a more extensive employment of the roofs of hospitals in the treatment, particularly of such patients whom the stimulation afforded to the bodily functions by a plentiful supply of good, fresh air may serve to tide over debilitating effects of a disease process. In the ordinary house the roof could be employed for similar purposes with very little trouble. It could be made to serve not only as a part of the sick chamber but also as a healthful playground and retreat for the family in general, where the wind and sun have free access, and the dust, so prevalent in the streets, is largely excluded. The Orientals have long regarded the roof as something more than a protection for the chambers underneath, and their custom in this respect is one we can well adopt with advantage.

THE QUESTION OF PURE MILK.

IN almost every part of the civilized world the problem of how best to secure as pure a milk supply as possible is exercising the minds of medical men and sanitarians. The problem has been partially solved in some countries, notably in Denmark, but in most other lands a contaminated milk supply constitutes a grave menace to the public health. Great Britain, especially, is very backward in this respect, and although the municipalities of certain of its large cities have taken up the matter, only the fringe of the evil has been touched, and the situation generally is bad.

Victoria, in Australia, has recently enacted legislation by which the government of that commonwealth will exercise a fairly rigid control over the milk supply. Such laws will undoubtedly do good. In some parts of this country the public milk supply is fairly satisfactory, but in other parts it is very much the reverse. Where the supply is good, the result has been brought about chiefly by private effort. Certain municipalities have taken the matter in hand, with a favorable outcome, but State legislation is needed throughout the whole country in order that the entire milk supply may be of a healthful character.

The Milk Commission of the Medical Society of the County of New York has done excellent work, but its field of operation is limited, and the milk having its certification is of a price which puts it beyond the reach of any but the rich or the extravagant. The chief value of the work of this Commission is by way of demonstration of what can be done by cleanliness in the dairy. Its inspectors cannot reach the main sources of supply, which are the small farms in New York State and Connecticut, some in this State being as far from the city as the shores of Lake Ontario, yet this individual inspection is the only way to insure purity in the milk supply of this or any other city. The Health Commissioner of New York has recently adopted the plan of inspection of the dairies and farms from which the milk supply of the city is derived, at the same time watching the dealers who handle the milk after it comes here. If this inspection is thorough, and includes all the one-cow to five-cow farms contributing to the flood of milk pouring into the city every day of the year, if the milk can be watched on the way, and if the dealers can be prevented from tampering with the milk in their shops, the city will be fortunate indeed.

That our supply is not yet what it should be every consumer of noncertified milk has daily demonstration, but the conditions are better than they were a few years ago, and Dr. Darlington is deserving of all praise for what he has accomplished. It is too much to hope, however, that his example will be followed by all the other health officers of the country, and one naturally turns to the federal government to protect the country at large from the dangers of milk poisoning. In a letter recently published in the MEDICAL RECORD, Mr. Cristadoro of Point Loma, Cal., suggested federal inspection of milk as the only means of insuring a pure supply, but we fear this is hardly possible. State supervision would be possible and more practicable, but even this would be difficult.

The problem of a pure milk supply is a large one, larger even than that of a pure water supply, and it is worthy of the study of the greatest of our sanitarians. We do not say it is neglected, for it is engaging the earnest thought of many in and out of the medical profession, but it does not receive the attention it deserves from the community at large. We are concerned about our canned meat, but meat is cooked before it is eaten, and however disgusting the thought of its preparation may be, the actual harm it does is as nothing compared to that from the drinking of raw milk, an ideal culture fluid for bacteria of all kinds.

MALARIA IN GREECE.

UNDER this title an interesting address was recently delivered by Ronald Ross before the Oxford Medical Society (*Journal of Tropical Medicine*, November 15, 1906). His attention was called to the subject by an invitation extended by a British company owning extensive tracts of land in Greece, and which endeavored to reduce the amount of malaria affecting its employees. The address is of particular interest, not because it adduces anything new in the medical line, but because it gives incidentally a well-considered plan of procedure for any one taking up the question of exterminating malaria anywhere. The first thing determined was the actual amount of the disease present among the company's people, and next the amount among the surrounding population. Finally a search was made for the insects which were the carriers of the poison. These were found in the customary shallow pools, and proved to be the larvæ of *Myzomyia maculipennis*, a known carrier of malaria. Ross also found that a local society had been formed and was taking the matter up in a practical way. Perhaps the most interesting part of the address refers to the possible connection of the disease with the decadence of Greece. After calling attention to her triumphs in art, philosophy, and other similar directions, Ross notes that suddenly a blight fell over all. "Was it due to internecine conflict or foreign conquests? Scarcely, for history shows that war burns and ravages, but does not annihilate. Or was it due to some cause entering furtively and gradually sapping away the energies of the race by attacking the rural population?" It is suggested that malaria may have been introduced into Greece about the time of Hippocrates by the numerous Asiatic and African tribes brought in as slaves by their Grecian conquerors. Supposing, continues Ross, "that, as is probable, the anophelines were already present, all that was required to light the conflagration was the entry of infected persons. Once started, the disease would spread by internal intercourse from valley to valley; would smoulder here and blaze there, and would gradually eat out the high strain of the northern blood. "Ross is confident that causes such as malaria, dysentery, and intestinal entozoa must have modified history to a much greater extent than we conceive." Our historians and economists do not seem even to have considered the matter. It is true that they speak of epidemic diseases, but the endemic diseases are really of greater importance. The same cause works the same evil in modern Greece. Though the country has been freed from the Turks for seventy years, yet its population has not increased very much. The inns are comparatively small and shabby and not likely to be frequented by many modern tourists, and the methods of communication are primitive. This is very surprising, because one would think that such a country would be the Mecca of all the tourists of Europe and America who would pour their millions of pounds into it just as they do into Switzerland. But, of course, the reputation of unhealthiness possessed by many of the rural tracts is fatal; the tourist thinks twice about going to them, and the innkeeper hesitates about spending his capital in a locality where he and his children may expect to be frequently ill." Fortunately, the remedy is one of easy application. Persistence of effort along lines already established will rid Greece of malaria. A return to its former glory, however, is hardly to be looked for in the immediate future, other factors conspiring to prevent such a resurrection.

THE COURSE OF THE TRAUMATIC NEUROSES.

THE uncertainty in regard to the prognosis in cases of neurosis consequent on bodily injuries is notorious, and attention has often been called to the prompt improvement in the patients' condition that frequently occurs after the award of pecuniary damages after a legal contest. In these cases the customary inference is that the plaintiff, on reaping the reward of what, to some extent at least, was malingering, drops the now no longer necessary pretense of incapacity and enjoys a much greater recompense than his actual condition warrants. Neurologists have pointed out that this is by no means always the case, and that these sudden cures are often not the result of the financial salve, but depend on the freedom from the feeling of uncertainty and constant introspection that a pending lawsuit for nervous injury always entails. This question, as it is constantly occurring in Germany in connection with the accident insurance laws, is discussed by Gaupp in the *Münchener medizinische Wochenschrift* of November 13, 1906. He attributes the steadily increasing frequency of cases of traumatic neuroses in no small measure to the manner in which these laws are framed and carried out. The long delays in making awards, and the frequently repeated examinations for the purpose of determining whether the patient's pension can be cut down, he considers do much to encourage the development of nervous incapacity and to retard recovery. As now executed, he says, these laws defeat the beneficent object for which they were enacted, and instead of serving to aid the indigent workman through a period of temporary incapacity, they tend to make of him a permanent nervous invalid unfit to work, or even to derive any satisfaction from the help he receives. He suggests among other things that the award to the patient, instead of taking the form of a regular stipend or pension, be made in the payment of a single lump sum, whose amount shall be determined by a

jury of three physicians, who shall make their final examination three years after the date of the injury. While the problem does not present itself in just this form to legislators and physicians in this country, another point made by Gaupp is of universal applicability, and that is that physicians, in examining patients after injuries, particularly if nervous symptoms are already present, should avoid any statements in regard to the possible course or outcome of the trouble which may serve to react upon the mentality of the patient in the nature of a suggestion. On the other hand, it is equally wrong to assume a manner which shall, as it were, force the patient to exaggeration of his ills in order, as he thinks, to make an impression on his medical adviser.

Pleurisy in Association with Cardiac Disease.

Pleurisy in association with cardiac disease has long been of interest to the physician. A suggestive paper on this subject is given by Ch. Roubier and Thévenet in the *Revue Française de Médecine et de Chirurgie* of October 25, 1906. The association of these two affections is not rare. The pleurisy may be either dry or there may be effusion. The dry pleurisy is frequent, but gives no marked symptoms. Pleurisy with effusion is of far more interest to the clinician than the other form. When the physician discovers a pleural effusion in a cardiac patient he should make up his mind whether he is dealing with a pleurisy or a simple hydrothorax. For a long time these two affections were not clearly differentiated. Pleurisy is encountered both in acute affections of the heart, such as acute pericarditis and acute endocarditis, and in chronic affections, such as myocarditis and valvular lesions. According to Huchard and Robert arterial cardiopathies are a more frequent cause of pleurisy than are valvular lesions. Barié, however, thinks that they occur more often in patients suffering from mitral lesions. They are also observed in lesions of the right side of the heart. All cases of pleurisy in cardiac patients are not due to the same cause. In some cases it appears that pericarditis plays a part in the development of the pleurisy; pleurisy consecutive to a pericarditis is noted almost always on the left. Likewise, the lesions of pericarditis, so frequent in the arteriosclerotic, may in some cases bring about a neighboring pleurisy. Most often, however, pleurisy is consecutive to an alteration in the subjacent pulmonary parenchyma. This alteration in the tissues varies. It may be in the form of passive congestion, active hyperemia, or spots of bronchopneumonia in the inferior lobes, and so on. But by far the most frequent form is the pulmonary infarct. In some rare cases there exists a latent pleurisy like that which is observed in certain cachectic conditions and in Bright's disease, or, more rarely still, a tuberculous pleurisy which may develop in patients weakened by cardiac disease. The diagnosis of pleurisy in the course of cardiac disease is easy or difficult, according to the case. The prognosis of such a pleurisy must be considered as very serious. Treatment consists in the evacuation of the liquid by a thoracentesis and in treating the cardiac affection by methods habitually employed.

The Etiology of Eclampsia.

It is a far cry from hay fever to eclampsia, yet these two apparently widely separated conditions are linked together by Weichardt in a discussion of the latter condition which he and Piltz have published in the *Deutsche medizinische Wochenschrift* of November 15, 1906. These authors state that a study of the mechanism of production of eclampsia and hay fever leads to the conclusion that each disease is the result of the formation of specific poisons from albumins, in the one case derived from placental albumin and in the other from the albumin of pollen. The serum obtained by injecting into rabbits placental cells or pollen grains, in each instance is not antitoxic but cytolytic, and cytolysins are formed which can break up homologous albumin molecules and liberate toxic groups or so-called endotoxins. It is Weichardt's belief that eclampsia is the result of the formation in the body of toxic substances resulting from the cytolysis of placental cells that enter the circulation, it being assumed that in these cases there is a deficiency in antiendotoxins or inhibiting bodies. By injecting into rabbits a specially prepared trituration of placental tissue the authors were able to satisfy themselves of the existence of such an endotoxin that appeared to present toxic components of two different types. The first of these was a hydrogel forming body which is therefore active in causing coagulation of blood, whereas the other more deleterious component has a specific affinity for the respiratory center, and when injected into animals promptly causes death through failure of this function. The authors also speak of their attempts to produce an artificial inhibitory body to be used as a prophylatic, in which they have been partially successful, though it does not appear that there is any immediate possibility of its being practically useful.

Diabetes and Mental Troubles.

The mere discovery of sugar in the urine of an insane patient does not offer sufficient ground for concluding that the insanity has been caused by the glycosuria. L. Marchand and Olivier, in an interesting paper on this subject in the *Gazette des Hôpitaux*, September 6, 1906, state that sugar is frequently found in the urine of the insane. Glycosuria, often intermittent, occurs temporarily as the result of various factors. It is necessary, then, before declaring that the mental troubles are due to glycosuria, to determine whether the glycosuria is intermittent or, on the contrary, continuous. Persistent glycosuria is rather rare in the insane. Lailler nevertheless thinks that this condition is found more frequently in the insane than it is in sane patients. The relations between diabetes and mental troubles may be arranged in several groups, which represent theories advanced by different authorities: Diabetes is of nervous origin; it is symptomatic of the cerebral affection, which is the cause of mental troubles; diabetes is the cause of insanity; diabetes and insanity are both under the influence of the same general disturbance of nutrition, and are simply concomitant; there is an alternation between the diabetes and mental troubles; insanity occurs in a diabetic without any relation between the two affections. It can be seen from these diverse theories how complex is the question of the relation between diabetes and mental troubles. The mental troubles which develop in diabetics are of the most varied character, and do not differ at all from those which are observed in the course of the various intoxications.

Chronic Icterus.

The persistence of jaundice during a period of years without impairment of the general health is a condition that has received but little attention outside of France. Nearly all of twenty-seven cases of this

sort of which the records have been collected by Claus and Kalberlah (*Berliner klinische Wochenschrift*, November 12, 1906), have been reported by French physicians, but the authors contribute to the number two additional cases of their own. These patients were brothers still in the twenties, with a family history of jaundice, who during a period of years had manifested continuous jaundice unaccompanied by serious general symptoms. As a result of their study of the reported cases of this condition the authors come to the conclusion that the affection does not occur under typical conditions, and that no general etiological factor exists. Some of the cases are congenital, and in these it appears that there is a primary change in the spleen, accompanied by deficiency in its function of the metamorphosis of blood pigment, perhaps also a congenital communication between the lymph channels and the bile passages. In those cases that appear later in life there is probably a primary lesion of the liver cells, possibly the result of infection or of toxin action. This view is substantiated by the frequency with which swelling of the spleen is noted, the rarity of hepatic enlargement, and the mildness or absence of subjective disturbances in the congenital cases, in contrast to the evidences of hepatic involvement that are common in the acquired form. It is not yet certain whether chronic icterus of this general type is actually commoner in France than in other countries, or whether French physicians merely have been more industrious than those of other nationalities in studying such cases, but it is not unlikely that if attention is directed to this subject many more similar observations will be reported.

The Use of Oil in Gastroduodenal Disease.

The favorable effects of oil in the presence of gastric hyperacidity has long been recognized. The sedative and anodyne action of oil on inflamed tissues is well known, and in the case of olive oil there is also a high nutritive value to be considered, so that it should prove of great use in gastric ulcerations. In a recent report by Merkel (*Deutsches Archiv für klinische Medizin*, Vol. 84, No. 1) we find that it may be given about half an hour before meals through a sound or by spoonful doses, and the administration kept up for from six to eight days together with lavage and an appropriate diet. In this manner the oil has been used with good success in cases of pyloric stenosis after gastric ulcer, chronic ulcerations with hyperacidity, pyrosis, and simple ulcer of the stomach. In the latter case it was possible to prevent entirely the occurrence of pain after eating.

News of the Week.

Health Conditions in the Canal Zone.—The great efficiency of the Isthmian health department is shown by the fact that according to a report the Isthmian Canal Commission has just received from Col. W. C. Gorgas, the chief sanitary officer on the Zone, not one American has died in the Canal Zone from disease during the last three months. The decrease in the death rate among the employees is due almost entirely to the decrease in pneumonia. In October the deaths among the canal employees included 86 negroes and 2 whites.

The Health of New York City.—The lowest death rate for the greater city since consolidation is that of the week just ended. It is 15.63, as against 17.82 for the corresponding week of 1905, a reduction in the number of deaths of 175, or 2.19 per cent. The death rate was especially low in Brooklyn, where the rate for last week was 15.34, as against 18.42 for the corresponding week of last year.

Coroner's Report of Cook County (Ill.) for November.—The 349 deaths investigated during the month show no causes which are not normal to a city like Chicago, and are seven less than those for October. Of this number of deaths, 110 were natural deaths, 25 were suicides, 28 were due to railroad accidents, 17 to asphyxiation, 14 to street cars, and 10 to homicide. Of the 25 suicide cases, 13 were the result of despondency. Four of the 25 suicide cases developed from temporary insanity, while 8 have not been accounted for. Shooting was the prevailing method of self-destruction. Fourteen used guns for suicide, 4 resorted to asphyxiation, 5 to poisoning, 1 to hanging, and 1 victim cut his throat. Among the homicides, 6 were murdered, 2 were victims of murder and suicide, while 2 were classed as justifiable murders.

A New Type of Influenza.—Press dispatches report that a typical form of influenza is very prevalent in Oxford and some other large towns in England. The chief symptoms are gastrointestinal, nausea and diarrhea being very severe, and as the health officials declare that the water and milk supplies are above suspicion, the physicians of Oxford are inclined to consider the affection as a variety of influenza. Students and townspeople have been equally affected, and hundreds have already been infected. The semifinal football match for the intercollegiate cup had to be postponed on account of the illness of a number of the players.

Fatal Cholera Inoculations.—The very promising experiments in the production of an anticholera serum that have been conducted in Manila under the supervision of Dr. Strong, chief of the Government laboratories, and carried on under the authorization of the Philippine Commission, have met with an unexpected check in the death of ten of the twenty-four native prisoners in the Bilibid jail, who were being experimentally inoculated. It is reported that the serum used may have become contaminated with plague germs during its preparation. Much protest was aroused in the Filipino press over the affair, and Governor-General Smith has appointed a special committee to investigate the deaths, and for the time being has revoked the authorization to perform experimental inoculations.

Yellow Fever in Cuba.—While new cases of yellow fever are still appearing in and about Havana, the situation is not regarded as serious. It is expected that the results of the mosquito-killing campaign instituted a month ago will soon be evident, for it has been found that thirty days is about the minimum of time in which the effects of the prophylactic measures become apparent. The sum of $30,000 is to be spent for the construction of three new wards for Las Animas Hospital.

International Tuberculosis Society.—At the meeting of this society held in Paris on November 6 under the presidency of Professor Lancereaux, among other matters the subject of the compulsory notification of tuberculosis was discussed by Drs. Samuel Bernheim and Louis Dienpart. These speakers strongly advocated the enforcement of legislation to this effect, and considered that prophylaxis could not be effectively carried out without such measures. Dr. Bernheim also pointed out the value of the phosphates and of creosote in the treatment of tuberculosis.

Child Labor Bill to be Introduced.—Senator Beveridge of Indiana has announced that he has prepared a bill to prevent the employment of children in factories, mines, and other establishments, and intends to push it vigorously. The bill prohibits carriers engaged in interstate commerce from transporting or accepting for transportation the product of any mine or factory in which children under the age of fourteen are employed, and concerns affected by it will be required to make affidavit every six months to the effect that they have no children under the prescribed age in their employ, and have not had during the preceding six months.

Longevity in Europe.—According to the investigations of German statisticians in regard to longevity in Europe, the German Empire, with a population of 55,000,000, has but 78 persons who are more than 100 years old. France, with a population of fewer than 40,000,000, has 213 who have passed their hundredth birthday. England has 146, Scotland 46, Denmark 2, Belgium 5, Sweden 10, and Norway, with 2,300,000 inhabitants, 23. Switzerland does not boast a single centenarian, but Spain, with about 18,000,000 population, has 410. The most amazing figures come from the troublesome, turbulent region of the Balkan peninsula. Servia has 573 persons who are more than 100 years old, Roumania has 1,084, and Bulgaria 3,883. In other words, Bulgaria has a centenarian for every hundred of its inhabitants, and thus holds the international record for old people. In 1892 there died in Bulgaria 350 persons who had lived for more than a century. The death of Jean Mignot of Montpont, who was probably the oldest Frenchman, has recently been reported as occurring at the age of 107 years.

Artificial Biogenesis.—At a recent meeting of the Academy of Sciences of Paris, Prof. d'Arsonval exhibited what appeared to be forms of vegetable life artificially produced by Prof. Leduc of the Nantes Medical Faculty. These were said to have been produced as the result of the inoculation of bouillon containing ferrocyanide of potassium and seasalt with a combination of glucose and a copper salt.

A Scholarship in Honor of the Curies.—Andrew Carnegie has informed the authorities of the University of Paris that he will present to the University a fund sufficient to yield $2,500 annually, to be used to pay for scholarships for research in the natural philosophy laboratory, which was recently created for the late Prof. Curie. In accordance with Mr. Carnegie's wishes, the scholarships will be named Bourses des Curie. They will be open to students of all nationalities. Mme. Curie was recently appointed Professor of Sciences at the University of Paris, the chair previously held by her husband, and commenced her lectures at the Sorbonne on November 5.

The Nobel Prize in Medicine.—It has been announced that the Nobel prize in medicine for the present year, amounting in value to about $40,000, is to be divided between Camille Golgi of Italy and Santiago Ramon y Cajal of Spain. The award is to be made in consideration of Golgi's work in perfecting the silver impregnation method for studying nervous tissues, and of Cajal's labors in applying the method to the investigation of the axis cylinder of the nerve cell.

Patent Medicines in Switzerland.—In spite of the opposition of the chemical manufacturers of Switzerland and Germany, the Swiss legislative committee appointed to consider this question has decided that in drafting the new Swiss patent laws, medicinal preparations shall not be included, and will therefore be unpatentable.

Opening of the Woman's Hospital.—The formal opening ceremonies of the new Woman's Hospital in the State of New York, at One Hundred and Ninth street and Amsterdam avenue, were held on Wednesday afternoon, December 5. The hospital was open for inspection all day on Wednesday and Thursday.

Dr. E. L. Hunt has been appointed attending neurologist to the City Home for the Aged on Blackwell's Island.

Dr. George Thomas Palmer, Assistant Secretary of the Illinois State Board of Health, has tendered his resignation as a member of that body, for the purpose of devoting all his time to journalism.

St. Luke's Hospital.—At a recent meeting of the Board of Managers of St. Luke's Hospital, Dr. S. W. Lambert was appointed attending physician to the hospital to succeed the late Dr. G. A. Spalding.

Examining Physicians for Bellevue.—At last week's meeting of the Trustees of Bellevue Hospital it was decided to appoint four examining physicians, at a salary of $1,000 a year, to take charge of the reception room of the hospital in six-hour shifts. Dr. Walter C. Cramp, Dr. H. L. Hobker, Dr. Leroy J. Smith, and Dr. A. J. Heitlinger, all recent graduates of the hospital, received the appointments.

American Society of Sanitary and Moral Prophylaxis.—A regular meeting of this society will be held at the Academy of Medicine on Thursday, December 13, 1906, at 8:30 P.M. The meeting will be under the auspices of the Committee on Education, and the general subject for discussion will be the matter of public school instruction in the physiology and hygiene of sex. Addresses will be made by Dr. Thomas M. Balliet, Dean of the School of Pedagogy, New York University, Dr. Burt G. Wilder, Professor of Physiology, Cornell University, and Dr. Helen C. Putnam, chairman of the Committee to Investigate the Teaching of Hygiene in Public Schools, of the Academy of Medicine. Dr. Prince A. Morrow will preside, and the secretary of the society is Dr. Edward L. Keyes, Jr.

Presbyterian Alumni Meeting.—At a meeting of this society to be held on December 8 at the residence of Dr. Linsly R. Williams, Dr. Richard C. Cabot of Boston will read the paper of the evening, entitled "Some Suggestions for the Reorganization of Out-Patient Medical Work." Drs. S. W. Lambert, W. Gilman Thompson, Theodore C. Janeway, hospital superintendents, and others interested in hospital work will take part in the discussions.

Northwest Texas Medical Association.—At the annual election of officers of this society held in Texarkana, November 22, the following were elected: *President,* Dr. Preston Hunt, Texarkana; *First Vice-President,* Dr. W. L. Baber, Winnsboro; *Second Vice-President,* Dr. H. Taylor, Marshall; *Secretary,* Dr. R. H. T. Mann, Texarkana; *Treasurer,* Dr. C. A. Smith, Texarkana.

International Medical Association.—At the second annual meeting of this society, held in the city of Mexico, November 15 to 18, it was decided to hold next year's meeting in Monterey. The following officers were elected for the ensuing year: *President,* Dr. H. V. Jackson, Durango; *First Vice-President,* Dr. Sidney Ulfelder, Mexico City; *Second Vice-President,* Dr. G. B. Hyde, Silao, Guanajuato; *Secretary and Treasurer,* Dr. J. S. Steele, Monterey.

Medical Council of Ontario.—The following candidates have been elected by acclamation to the Medical Council of Ontario from the territorial divisions named: Division No. 1, Dr. J. L. Bray, Chatham; 3, Dr. J. McArthur, London; 4, Dr. J. A. Robertson, Stratford; 6, Dr. Henry, Orangeville; 7, Dr. P. Stuart, Milton; 8, Dr. S. H. Glasgow, Welland; 10, Dr. E. E. King, Toronto; Dr. H. Bascom, Uxbridge; 13, Dr. S. C. Hillier, Bowmanville; 14, Dr. A. E. MacColl, Belleville; 15, Dr. W. Spankie, Wolfe Island; 16, Dr. J. Lane, Mallorytown; 17, Dr. M. O. Klotz, Ottawa.

Obituary Notes.—Dr. Peter W. Ray, a colored physician of Williamsburg, died on November 27 of heart disease, at the age of eighty-two years. He began his medical training in Bowdoin College, Me., and was graduated from Castleton College, Vt., in 1850. He was one of the founders of the Brooklyn College of Pharmacy and of the King's County Pharmaceutical Society, of which organization he was treasurer for twenty-three years.

Dr. Florence G. Emerson, the wife of Dr. Frank S. Emerson of Williamsburg, died of pneumonia on November 26. She was graduated from the Women's College of the New York Infirmary for Women and Children twelve years ago, and for the past ten years had been medical inspector for the Health Department in Brooklyn.

Dr. Percy Linwood Tantum of this city died on November 26, at the age of forty-five years. He was a son of the late Dr. John Roslyn Tantum of Bordentown, N. J. He was a graduate of the University of Pennsylvania, and received his medical degree from the Jefferson Medical College.

Dr. Glover Crane Arnold of this city died on November 29, at the age of fifty-seven years. Dr. Arnold was born in Charleston, S. C., and was graduated from the Bellevue Medical College in the class of 1873. He had for years been instructor of anatomy in Bellevue Medical College, and retired from active practice about four years ago.

Dr. Edward J. McDonough of this city died on November 29, at the age of forty-four years. He was graduated from the New York University Medical College in the class of 1887.

Dr. J. M. Miller of Springfield, O., died on November 26 as the result of septicemia from a carbuncle, at the age of seventy years. He was born in Nuremberg, Germany, but came to this country at the age of nineteen years, and received his medical degree from the New York Homeopathic College in 1873. Two years later he went to Springfield, where he had practised ever since. Dr. Harry T. Miller of Springfield is his son.

Dr. S. E. Solly of Colorado Springs, Col., died of tuberculosis at Asheville, N. C., on November 20, at the age of sixty-two years. Dr. Solly went to Manitou in 1875, but shortly afterward removed to Colorado Springs, where he devoted himself especially to the treatment of tuberculosis and to the study of climatology, on which latter subject he had written a book. Dr. Solly was an ex-president of the American Climatological Association, ex-president of the American Laryngological, Rhinological, and Otological Association, director of the National Association for the Study and Prevention of Tuberculosis, ex-president of the Colorado State Medical Society, and twice president of the El Paso County Medical Society.

Dr. James William Claiborne of Petersburg, Va., died suddenly on November 22 at the age of eighty-one years. He was born in Richmond, and after studying medicine at the Richmond College of Medicine, received his degree from the University of Pennsylvania. In 1849 he went to California, but returned at the time of the Civil War and served as division surgeon in Mahon's brigade. At the close of the war he resumed practice in Petersburg, and had been engaged in active work up to the time of his death.

Dr. R. W. Southgate of South Weymouth, died suddenly of heart failure on November 22, at the age of forty-six years. He was a native of Dedham and had practised for six years in Rockland. Two years ago he removed to South Weymouth.

THE THIRD HARVEY SOCIETY LECTURE.

The third regular lecture in the course given under the auspices of the Harvey Society was held at the Academy of Medicine on Saturday, November 17. The speaker, Professor W. T. Porter, of Harvard University, took for his subject "Vasomotor Reflexes." He began by saying that the physiological demonstration of a vasomotor mechanism inaugurated the really modern study of the physiology of the circulation innervation. Prior to 1851 it had been known that the blood-vessels possessed contractile walls and that they contracted when mechanically stimulated as by scraping. Furthermore the sympathetic nerves had been traced to the blood-vessels until lost in their finest ramifications.

Prof. Porter then discussed the landmarks of this physiological demonstration, beginning with the decisive demonstration in 1851 by Claude Bernard of the relation between the sympathetic nerves and the circulation. As all know, this was done by cutting the cervical sympathetic and finding that there was a more active circulation on the corresponding side of the face and the ear, with also an increased local temperature. In 1852 Brown-Séquard had found that, if the superior portion of the cut sympathetic was stimulated, the dilated vessels of the face and ear contracted, the parts supplied becoming paler and cooler. Bernard had obtained similar results independently. In 1856 Schiff had shown that destruction of parts of the spinal cord caused the same vascular dilatation and rise of temperature following section of the vasomotor nerves outside of the cord. Certain vasomotor nerves therefore take their origin in the cord. Subsequently it had been shown that these nerves left the cord by way of the anterior roots. Schiff had suggested the existence of vasodilator nerves and this had been demonstrated as a fact by Bernard's classic experiments on the chorda tympani. In 1876 Goltz, in Leipzig, had shown that the vasodilators were found in many special nerves; by cooling the tissues supplied and stimulating the peripheral end of a mixed nerve a vasodilatation was obtained, while on warming the tissues a constriction of the vessels resulted. In 1877 Bernstein had differentiated the two types of nerves by their rate of degeneration after section. Bowditch and Warren then showed that weak electric currents affected the dilators; stronger stimulation brought about constriction. The effect of stimulation had been shown to be prolonged on the dilators.

Continuing the historic development the speaker pointed out that the demonstration of vasoconstrictor and vasodilator fibers in the nerves had led to study of the centers controlling these. Goltz had shown that constrictor impulses proceeded from the spinal cord. Other investigators

then demonstrated the existence of reflex points, stimulation of which produced localized vasomotor changes in other tissues of the body. These were the well known experiments with various erectile organs. Owsjannikow and later Dittmar had worked to determine the position of the constrictor centers. The former had introduced the method of successive sections, dividing the bulb transversely at various levels, separating the medulla from the pons and sectioning downward. In this way he approached almost the calamus scriptorius without influencing blood pressure. When, however, the section fell nearer the cord a considerable and permanent fall in the blood pressure resulted. Sectioning from below and stimulating caudally gave similar results. These observations had established that the vasomotor area in the rabbit extends over about 4 millimeters of the bulb. It maintained the general vascular tone of the body. Dittmar had shown that the constrictor center was bilateral, lying in the columns on both sides of the median line.

There were vasomotor centers in the spinal cord also, the speaker continued. Goltz had shown that after division of the spinal nerves the vasoconstrictor impulses were only temporarily cut off. Constriction of the vessels gradually occurred. After some days the circulation had apparently returned to the normal condition. The same observer as well as others had also demonstrated the exercise of vasomotor centers in the dorsal and lumbar region.

Much less was known with regard to the dilator centers. As early as 1874 Goltz had shown the existence of such a center in the lower cord. It had also been found that stimulation of the central end of the sciatic nerve, after section of the spinal cord, might cause reflexly a dilatation of the vessels of the opposite limb. There was additional evidence pointing to the existence of a vasodilator center. Certainly it had been clearly established that vasomotor cells are present in the spinal cord.

The speaker next discussed the experiments of Goltz and Ewald, which showed that the vasomotor tonus maintained in the hind limbs by the spinal cord may be regained some days after destruction of the lower portion of the cord. Even after destruction of both bulbar and spinal centers the tonus of the blood-vessels could still be maintained. The same results had been arrived at by Gley and Sherrington. The sympathetic ganglia were therefore probably centers of reflex motor activity and could compensate in case of injury to the higher seats in the cord and bulb. Golz had also shown that removal of a section of the sciatic nerve is followed by a gradual return of the tonus of the vessels. This suggested that in the blood-vessels themselves there was a mechanism that regulated the tonus. With this résumé of the important epochs in the history of vasomotor reflexes the speaker came to the "modern period" of the past few years.

The work of Langley was cited as having enriched our present knowledge. This observer had found that the injection of nicotine into the circulation prevented, for a time, the passage of nerve impulses through the sympathetic cells. The fibers peripheral to the cells were not injured. Efferent stimulation of the lumbar cord (proximal to the sympathetic ganglia) resulted in no change in the tonus of the vessels ordinarily affected. The end result of these and the earlier studies had been the demonstration of three neurons as the connecting paths of the vasoconstrictor system: (1) The center near the calamus scriptorius with the axis cylinders running in lateral areas of the cord and communicating with (2) cells lying in the cord; the axis cylinders of the latter pass through the anterior roots to the sympathetic ganglia and end in contact with (3) the neurons whose axes extend to the muscle-endings in the walls of the blood-vessels.

The speaker referred to the attempts which had been made to find centers in the cortex of the brain for vasomotor regulation. Results of experiments on blood changes originated by cortical stimuli or injury were probably not associated with a localized center, but with reflexes afferent to the lower centers. The brain should be considered as a multiple organ or as a collection of numerous individual organs; the irritation of one part could reflexly excite another part, and thus give rise to a manifestation of function by the latter. Upon removal of the brain the vasomotor system no longer operated with the normal restraint. It had been shown, for example, that the blood pressure rose on removal of the cerebral hemispheres. In the Harvard laboratory it had been found that vasomotor effects were more easily produced by stimuli after the brain had been removed; the centers were mroe irritable. It was possible, the speaker said, that the remarkable reflexes (syncope, shock, etc.) resulting from ether administration were due to the excluding effect of the ether on these higher centers.

In asphyxia after the separation of the cord from the brain it had been noted that vasoconstriction was produced reflexly through the spinal centers, though the reaction time was slower in the case of the spinal cells than it was with the bulbar cells. Asher and Arnold had shown that when the spinal cord was destroyed, this constriction could not be reflexly effected through the cells in the sympathetic ganglia. This constituted a fundamental difference from the vasomotor neurons of the two larger centers.

The condition of the blood pressure could also be influenced independently of the vasomotor centers. This was illustrated by noting the effect of changes in the tonus of certain vessels with and without splanchnic section.

According to the speaker one of the problems at present yet unsolved was whether the vasomotor centers were truly automatic or whether the impulse discharges were regulated reflexly or perhaps by a summation of afferent stimuli. Another problem lay in the probability that afferent impulses reach a relatively small number of cells collected into groups. There was some evidence that the vasoconstrictor nerves supplying large areas were so divided that certain associated cells in the centers presided over local vascular areas. It was a further question whether or not a portion of the neurons in the vasomotor centers were set aside for the purpose of regulating blood pressure in the locality controlled by that group of cells. Another field of research, the speaker pointed out, was the relation of the vasomotor system to neuroses. Lapinski had recently, in *Virchow's Archiv* described researches from which he concluded that these disturbances were associated with changes in the neurons.

In conclusion, Prof. Porter gave some original considerations on the nature and cause of shock. The definition of shock was varied. There was a confusion of changes in the nervous system

with profound changes in the circulation. The speaker referred to the marked lowering of the blood pressure and weakening of the heart's action with pallor, etc., without actual mechanical injury to the nervous system; the anemia produced through lowering of the pressure was the immediate cause; no other fundamental functions were directly involved. Was shock due to the exhaustion of nerve cells or to some other cause? If due to exhaustion, afferent stimulation of the depressor nerve should give no further fall in the blood pressure. Experiments had shown that the same effect was produced if this were done; therefore there was no exhaustion. The speaker believed that shock depended upon an increased irritability. Afferent impulses under these circumstances were more effective than ordinarily. Strychnine produced a marked tendency to shock, while morphine, by depressing the irritability, exerted an antishock action.

Correspondence.

PANCREATIC FERMENTS IN THE TREATMENT OF CANCER AND THEIR ROLE IN PROPHYLAXIS.

To the Editor of the Medical Record:

Sir:—In the interests of medical science as well as in those of suffering humanity the following brief report of facts is made. A full and detailed report of cases with technique will be presented, later on, to the Academy of Medicine or directly in the pages of the Medical Record.

Two illustrative cases will be briefly mentioned: one a postoperative (two operations), and now inoperable cancer of the tongue; only a stump left. Recurrence characterized by all the distressing and loathsome symptoms of the disease. Treatment instituted in February, 1906. No treatment has been given since June, save ferment mouth washes. The patient is now living in good physical condition and keeping appointments with her dentist to have teeth, lost by ravages of the disease, replaced.

The second illustrative case is one of postoperative and inoperable cancer of the rectum, artificial anus. There were three operations, the last nine months since. At that time the mesenteric glands were found enlarged and indurated. Pain, which had persisted for two years necessitating the use of opiates, increased, and when the patient was first seen, six months since, the characteristics of progressive malignant disease were present. There were obstinate constipation, loss of appetite, strength, and flesh, pain, discharge, odor, sense of weight, bearing down, and a sinking feeling in the pelvis, with inability to stand or walk save for a few moments only, and very short distances. Length of life was estimated by the surgeon at one year, but the patient grew rapidly worse, leading the family physician to put it at from two to three months. From my own clinical experience in similar cases I felt that at least six months and possibly a year of life remained. The feeling in the rectum had varied during the interval between the first and last operation from that of a soft, flexible condition to at the last that of a pelvis in which there was old chronic induration. Masses began to develop in the rectum soon after the last operation. At the time of beginning treatment by pancreatic extract (Fairchild's), as originated by Dr. Beard of Edinburgh, rectal examination gave to the finger the sensation of passing through a narrow canal surrounded by hardened plaster-of Paris, save at the site of the original lesion, one and a half inches from the internal sphincter, where the tissues were, in addition, in a condition of cauliflower excrescence. The examining finger and the irrigating catheter penetrated at that time to a depth of about four inches.

Treatment has been thorough and vigorous. No clinical detail will be given until the cases are reported fully. Suffice it to say that at the present time a No. 12 catheter can be passed for purposes of irrigation, almost its entire length. Masses have been absorbed and eliminated; the rectal tissues are soft and flexible; the cauliflower condition has undergone tumefaction, degeneration, and elimination—in part, by its being thrown off per rectum, and indirectly by absorption. The patient walks, drives, does some professional work, eats most heartily, functions well, and has gained in physical strength and mental vigor.

While I do not report the case as cured, I must, in justice to Dr. Beard and his claims, state that the patient presents no clinical symptoms, objective evidence, or pathological findings of malignant disease.

The pathological findings of the discharges thrown off by rectum as the result of the treatment are reported as follows by Dr. W. M. Higgins:

"Specimen No. 6792. Examined for Dr. Cleaves. About ten c.c. of yellowish brown semifluid matter. Contains a number of flakes of mucopurulent material.

"Microscopical examination: Degenerated pus and epithelial cells mixed with red blood cells and mucus. Most of the cellular matter is degenerated leucocytes. The epithelial cells are few. Many of the cells are so broken down that it is impossible to classify them exactly. The red blood cells are quite numerous, many more than in the preceding specimen. Bacteria are negative. No tubercle bacilli.

"Diagnosis: Mucopurulent matter mixed with blood."

"Specimen No. 6793. Tissue. Dr. Cleaves. Gross appearance: Small piece of dark-gray tissue about three-eighths of an inch in diameter, moderately firm and friable. Received in formalin.

"Microscopical examination: The specimen shows a mass of glands similar to the glands of the rectal mucosa supported by strands of connective tissue. There is a large number of polynuclear leucocytes mixed with red blood cells scattered through the sections, especially in the fibrous trabeculæ. The tissue is somewhat degenerated, being stained with difficulty, but the outline of the glands and cell structure are quite distinct. There is no appearance of active proliferation of the epithelium, the acini being intact.

"Diagnosis: Adenoma with simple inflammation."

Summary.—This patient had adenocarcinoma of the rectum—a section made at the time of the original operation was examined microscopically, Massachusetts General Hospital—and is at present passing per rectum a discharge which has been repeatedly examined with the results above given. These, as will be seen, are absolutely negative so far as any cancerous condition is concerned. On the contrary, specimen 6793 is shown to be an absolutely benign adenoma.

Prophylaxis.—Adenoma of the intestinal canal calls at once for a bad prognosis. There are two theories as to adenomata: (1) That they are malignant *per se, i.e.* never originating as a benign tumor; (2) that they are benign from the first and take on malignancy as a result of some exciting cause—a breast injury, for example. The first theory fits in with Dr. Beard's theory of the trophoblastic or asexual nature of cancer.

From the character of the tissue thrown off in this rectal case it may be inferred that in the pancreatic ferments there is to be had an agent capable of keeping an adenoma from merging into an adenocarcinoma, and therefore they are to be regarded at least as prophylactic against the development of malignant disease. In any event, it behooves us, as physicians, to test this measure fully, and that speedily. Could the patients in these two illustrative cases have achieved the same results without mutilation what a blessing to them.

In conclusion I can do no better than to quote from a letter written to me by Dr. Beard: "In development all asexual structures, ganglion-cells, trophoblasts, etc., go on flourishing for a certain time, and then, *quite suddenly,* they commence to fade and degenerate. The death is a sudden one. There is no standing on the order of their going; they are *told to go—at once!*" He also authorizes the statement that "in neither case will the tumor ever recur." Upon that he will stake his scientific reputation.

Margaret A. Cleaves, M.D.

616 Madison Avenue, New York.

TWO CASES OF CANCER TREATED BY THE INJECTION OF PANCREATIC EXTRACT.

To the Editor of the Medical Record:

Sir:—I have been very much interested in Prof. Beard's studies and experiments along this line, though not having access to the full literature of the subject. The paper of Dr. Clarence C. Rice in the Medical Record of November 24, 1906, has prompted me to give two experiences in cases of undoubted cancer in which examination of particles and masses of the growths made the diagnosis certain. It is a fascinating field to cultivate—the possible treatment of malignant growths in this manner. In relating the following cases my object is simply to place the facts before

the reader, he to judge for himself of the remedial action of the injection on its merits:

Case I.—Mrs. B.; widow; aged 58 years. She has two children, 36 and 40 years of age, respectively. She is a strong, powerful woman, weighing from 150 to 160 pounds when in health. Two years ago she suffered from hemorrhoids and went to a specialist and had them injected, but without much, if any, relief. A year and a half later she went again to have the piles treated, but was sent back, as nothing could be done. She was examined by several competent surgeons, all pronouncing the growth cancer, and inoperable. On March 10 of this year she came to me for examination. I found a mass four inches wide, and of considerable length in the bowel extending from about three inches above the sphincter, up into the sigmoid portion of the gut. The growth was irregular, easily broken down, and of the usual cancerous odor. Masses passed with the stools, and at intervals with mucous and watery discharge. The patient had heard of the trypsin treatment and wished it used. The next day I began the treatment, injecting every other day first five, then ten, and finally twenty minims at a sitting, into the buttock. The injections were continued for six weeks, then at intervals of a week. The general health, which was very poor, improved remarkably; the flesh increased, the mucous discharges were augmented for about two weeks, while at the same time large masses of the diseased tissue sloughed off, pieces coming away nearly every day, and occasionally several times a day. The discharges then practically ceased (there having been none whatever for two weeks), and her health was so much improved that she took a trip to the Pacific Coast, staying most of the summer. She declared she felt better than she had in five years. She returned one week ago for further treatment, as some of the discharges were again troubling her. The growth is still there, but of reduced size.

Case II.—Mrs. R.; 36 years of age; married; no children; school teacher by profession. She has always been a frail, sallow, flabby, weakly woman. She suffers from excessive flooding at each monthly period and has pains to such an extent that she is forced to take morphine. She had been examined and a diagnosis was made of uterine cancer; this involved so much tissue, and was bound to the pelvic walls to such an extent as to preclude the thought of operation. The patient came to me three months ago for examination, and I found the condition as stated above, with an everted, raw, bleeding os. I used the injection direct into the growth and lower uterine tissue. Patient is irregular in attendance at treatment, coming as it happens. The present condition of the os is to all appearances healthy; at any rate; it is down to normal size, and the ulcerated surface has healed perfectly. Her condition generally has improved, though there is a hardened and apparently an agglutinated condition of the pelvic contents. This patient received but ten minims as the maximum dose, beginning as in the first case with five. The first patient took holadin capsules for a time, but thought they disturbed the stomach, and stopped. The second patient did not use them. The general health of this woman did not improve so markedly as that of the first, but the disease was influenced fully as well. F. B. Golley, M.D.

116 Grand Avenue, Milwaukee, Wis.

SURGICAL OPERATIONS IN TWO STAGES.

To the Editor of the Medical Record:

Sir:—Your comments on Professor Chetwood's suggestion that prostatectomy may in certain instances be done in two stages with greater safety than where a long and more radical operation is completed in a single séance, may well apply to other surgical procedures.

It is especially applicable to operations upon the brain, where a large area is to be exposed. The extensive horseshoe-shaped incision through the scalp and cutting through the skull always require very considerable time. In fully 50 per cent. of the operations of this character that I have performed within the last twenty years I have stopped the first procedures as soon as I had completed the cutting through the bone, packing the wound with sterilized gauze, and using moderate compression by bandage to arrest bleeding. Twenty-four or forty-eight hours later the operation is completed.

The results after this method have been much more satisfactory than in the early operations done in a single séance. With the modern methods of anesthesia, where ether narcosis is preceded by the inhalation of nitrous oxide gas, the majority of patients will not object to a repetition of the narcosis.

May I add here that the employment of Professor Dawbarn's method, confining a portion of the blood in the lower extremities by an Esmarch bandage thrown around the thigh at the groin, is of inestimable value in decreasing the hemorrhage from the head and neck.

John A. Wyeth, M.D.

244 Lexington Avenue, New York.

PRIORITY IN THE TWO-STAGE OPERATION FOR THE REMOVAL OF THE HYPERTROPHIED PROSTATE.

To the Editor of the Medical Record:

Sir:—In the Medical Record of November 24 there is an interesting editorial on the subject of "Prostatectomy in Two Stages," based upon a recent paper by Dr. Charles H. Chetwood. In calling attention to the great value of this procedure you give Dr. Chetwood credit for having originated the method. Kindly permit me to state a few facts in regard to this matter.

On the first day of February, 1905, before the New York State Medical Society, at its meeting in Albany, I read a paper on the enucleation of the prostate through a suprapubic incision. The paper was subsequently published in the *Annals of Surgery* for April of the same year. Two-stage prostatectomy is spoken of in this paper, and its advantages discussed for the reason that I had for a number of years given this operation preference in cases complicated by severe cystitis or by hemorrhage, and in exceptionally feeble individuals. I believed at the time that the method was original with me, and, while I have not fully examined the literature, I have not in casual reading come across any reference bearing upon the subject. Dr. Chetwood was present at the Albany meeting and read a paper there. One week later he performed the first step of the operation in the first case recorded in the paper which inspired your editorial.

This letter is not written with the idea of calling Dr. Chetwood to account, but merely to state facts. Dr. Chetwood may not have heard my paper, or, having heard it, he may have made subconscious note of the point in question. My first two-stage prostatectomy was performed at Mount Sinai Hospital in the autumn of 1896.

New York. Howard Lilienthal, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

RECTAL ALIMENTATION—[illegible] MICE—NOTES AND HEALTH—HYGIENE AND DISEASE TEACHING—COLLEGE OF SURGEONS' MEETING—OBITUARY NOTES.

London, November 17, 1906.

Rectal alimentation is a subject on which very diverse opinions are met with. Many doctors, influenced by the records of physiological research, have lost much of their faith in its value, though they continue to resort to it in certain cases. Others, basing their opinions on clinical observation, regard it as an invaluable resource. Seeing that it has kept its place for many generations, it is time that these divergencies disappeared. A step in this direction was taken by Dr. Seymour J. Sharkey in the Bradshaw lecture which he delivered at the Royal College of Physicians on the 6th inst. To show the extraordinary divergencies in the views of those who have investigated the subject, he quoted freely from French and German literature. Englishmen have not contributed much to it. While it is denied that proteids, starches, sugars, and fats can be supplied to the circulation by way of the bowel, everyone knows that water and certain salts may be absorbed. Many assert the enema owes its virtue to these alone, for they cannot deny its beneficial influence in certain cases—indeed, patients have been fed per rectum for a period of three weeks without losing much weight. It is generally agreed that the large intestine has little, if any, digestive power, but absorption certainly goes on in it. The colon receives the contents of the small intestine in a fluid form, and normally they become solid. With the water absorbed to produce this effect it is probable, if not certain, that some relics of earlier digestion are taken up. Clinically, pints of fluid are injected in the twenty-four hours and totally disappear. But though some food may thus pass in, it is not proved that sufficient can thus be introduced for the nourishment of the body. Peptones might be expected to be absorbed most easily, and it has been shown that peptones and albumoses can replace albumin in nutrition. They are taken up by the bowel, and most experimenters agree that they are not excreted unchanged by the kidney when thus given, though they are if injected into the blood. The peptonizing may be carried on in the bowel, but if one could rely on ready prepared pep-

tones they would be more convenient. Leube's injections (meat or fat with pancreas) demand much care in preparing. The extent to which fat can be utilized is not settled, and the same may be said as to milk. On the other hand, carbohydrates are generally acknowledged to be most valuable. Pure grape sugar is next to water the most easily absorbed.

Having considered these and other points, Dr. Sharkey referred to the confusion that results from not distinguishing between the clinical and experimental side. In the latter we read about the possibility of completely nourishing persons per rectum, but clinically that is not what is wanted. Rectal feeding generally is needed only for a time, and surgical progress tends to shorten the time and decrease the number of patients who formerly had to depend on it. Gastric ulcer is the most important, and Dr. Sharkey has found the treatment proposed by Dr. W. Pasteur most effectual, that is, perfect rest to the stomach for seven or ten days, or even more, the necessary water being given per rectum, ten ounces every four to six hours at a temperature of 100° F. Patients are comfortable and do not suffer from hunger or thirst, and the advantages over nutrient enemata are considerable. In some cases treated with nutrient injections, Dr. Sharkey gave water between them so as to make up the total fluid to about three pints. Analyses of matter returned from the bowel when washed out after nutrient enemata for twenty-four hours were made by Dr. Le Sueur, chemical lecturer at St. Thomas' Hospital, and the results compared with those of other observers. On the whole, Dr. Sharkey concludes that peptones, sugar, and powdered casein are the best constituents for use in rectal feeding.

We have heard a good deal of late about mice in connection with cancer, for the subject has been taken up by the ubiquitous reporter in the interest of certain newspapers. It is well, therefore, that the view commonly, perhaps too hastily, accepted concerning Jensen's mouse tumor should be subjected to searching criticism, and this it received in a paper by Mr. Roger Williams, read at the Pathological Society. He denied that this growth is a carcinoma, or even malignant, and was supported by Dr. Lazarus-Barlow. The tumor was first discovered by Morau in 1891, and subjected by him to experimental tests. Jensen followed him ten years later, repeated the tests, and popularized Morau's discoveries. Mr. Williams says the mistake of those who identified Jensen's tumor with cancer arose from trusting altogether to histological appearances—so often fallacious. Among previous errors thus arising, he named the contagious venereal tumors of dogs and coccidial disease of rabbit's liver. Of the former, specimens were shown at the Society a few years ago and accepted as cancer. Now that that fallacy was exploded it was disappointing to find experimentalists lapsing into the same error. A typical epithelial ingrowth and other quasimalignant appearances were common in many noncancerous conditions, *e.g.*, erosion of os uteri, blastomycetic dermatitis, etc. Jensen's tumor differs from cancer in being highly contagious, prone to set up epidemics, inoculable to other mice, and often spontaneously disappearing. In artificial transmission it will often change its type and lose its contagious property; it is circumscribed and can be enucleated; it does not impart cancerous properties to its host, nor does it cause cachexia. In all these crucial diagnostic points it differs from human cancer, and regarded as such it is a myth, a series of myths indicative only of the prepossession of the moment. Just now experimental cancer research was a medley of chaos, clouds, and tongues, giving neither light nor learning. Dr. Lazarus-Barlow agreed with the paper as to the nature of Jensen's tumor, and said the imitation of the carcinoma to sarcoma under transplantation by Ehrlich proved this. He had, however, not found it so easy as stated to infect mice with the growth.

On Monday there was a conference at the Medical Society of London to consider the noise problem of the metropolis. Sir Theodore Martin presided and made a bitter complaint as to the apathy of the authorities. He described himself as a victim to the misery inflicted by those "awful machines," motor omnibuses. A letter which he had written about them in July drew from the Chief Police Commissioner the most extraordinary admission for a public official. He admitted that he had the power to stop the juggernauts, but he had not stopped them, because he wanted, he said, an experiment made in the new method of locomotion. Sir Theodore said he could not open a window in his house owing to the stench of these vehicles; in bed he was badly shaken; double windows were no use; his ceilings were all cracking; many of his friends with long leases were being tortured and slowly killed by the Chief Commissioner's experiment. Sir Dyce Duckworth moved that the present excess of noise in the public thoroughfares is such as to cause disastrous consequences to the health and vitality of the people, and legislation is urgently needed. He was of opinion that no language could exaggerate the nuisance of the noise and stench which were grievously affecting the health of the community. Dr. John Anderson and Dr. Parkinson spoke to the same effect, and also of the terrible injury to property in the streets through which the cars ran. A second resolution carried unanimously, as was the first, called for legislation to prevent street shouting and music; to control all vehicles as to speed, and prohibit noisy traffic in residential streets from midnight to 5 A.M. Dr. Hyslop, in proposing this, said motor 'buses should run in underground drains, like other nuisances. Dr. A. Luff said he was sure many motor drivers were suffering from carbonic oxide poisoning. Dr. Radcliff Crocker urged that there should be a separate body charged with traffic regulation. The Chairman hoped that a carefully drawn bill would be submitted to Parliament dealing with every kind of noise nuisance.

A deputation headed by Sir T. Barlow and Sir V. Horsley, and containing a number of eminent doctors, waited on the Minister of Education on Monday in favor of teaching temperance and hygiene in elementary schools. Mr. Birrell professed sympathy, but gave little other encouragement. He said there was not a parent in the country who did not think he knew as much as most doctors about health and temperance, and, he added, they had some support in their opinion in the differences of doctors. If the bill before Parliament became law there would be medical inspection, and he expected benefit from the visits and advice of these inspectors. They must educate the public, and to do so must avoid technicalities and physiological jargon.

Yesterday the annual play at the College of Surgeons was duly performed for the twenty-second time. The president, Mr. H. T. Morris, placed the report before the meeting and made a brief statement as to some matters which had come before the Council. Then a resolution was proposed and carried unanimously affirming once more that members ought to be represented on the Council, which does not, as now constituted, represent the whole corporation. Other resolutions were passed, but what matters? The Council has persistently ignored the claim of members, and shows no sign of relenting.

Deputy-Surgeon-General Julius Wiles, late Rifle Brigade, died in the West London Hospital on Saturday as the result of a street accident. He was in his seventy-ninth year. He served with distinction in the Crimea, the China war of 1860, and the Ashantee war of 1874.

Department-Surgeon-General Sampson Roch, late of the Army Medical Staff, died on Friday, aged seventy-seven. He entered the service in 1854 and served through the Crimean campaign; received Turkish medal, clasps, etc. He retired in 1881, and afterwards acted as Medical Officer of Health for Cheltenham.

Dr. Lindsay Maclean died October 19, aged seventy-six. He retired from practice a few years ago. He edited *Echoes of Service* from the time he started it, thirty-five years ago, up to his death. It was devoted to medical missions in which Dr. Maclean was deeply interested. He was M.D. Edin. 1861.

Dr. Spencer T. Smyth, F.R.C.S., many years surgeon to Yarmouth Hospital, died October 26, aged eighty-six. In 1849 he was surgeon to the Cholera Hospital, and he held various appointments until his retirement some ten or eleven years ago.

Dr. R. Hamilton Bell, M.B. Cantab, etc., Physician to the Samaritan Free Hospital, the British Lying-in Hospital, etc., died on the 29th ult. of pneumonia, cut off at the age of thirty-five, after by his learning, talent, and energy he had established a position as one of the most rising obstetric authorities.

The following deaths are also announced: Dr. Lewis Smythe, on 29th ult., in his eighty-eighth year, M.D. of Glasgow 1840; Lieut.-Col. Robert Collins, late A.M.S., on the 31st ult., aged sixty-nine; Dr. John Roberts, on the 31st, at Salisbury, aged eighty-five; Dr. Douglas Kerr, at Bath, on November 14, aged forty-nine.

Remote Results of Conservative Operations on the Genital Organs of Women.—Loumeau, after making a careful study of this subject, has written a thesis in which he gives the opinions of the majority of surgeons of recent times. He concludes that when the adnexa of the two sides are removed, the uterus should be removed at the same time, since its presence is accountable for pain and bloody and leucorrheal discharges, and since its presence necessitates sometimes a secondary intervention. Partial resection and ignipuncture of the ovaries may be practised in cases of sclerocystic ovaritis, providing the tubes are healthy and permeable. When, during the course of an operation on the adnexa of one side, the tube and ovary of the opposite side are found to be affected, even if only slightly, it is not of advantage to preserve them. For a hypothetical pregnancy, one will often expose the patient to a bad therapeutic result and even to a second intervention. —*Journal de Médicine de Paris.*

Progress of Medical Science.

Boston Medical and Surgical Journal, November 22, 1906.

The Cause of So-called Habitual Lateral Curvature of the Spine.—This question is discussed in an elaborately illustrated paper by Max Böhm. The main thesis of the author is thus expressed: That developmental error of the human body in embryonic life which has its morphological expression in the so-called "numerical variation" of the spine, causes under certain circumstances those idiopathic lateral deformities of the spine which manifest themselves in the first half of the second decade of life, and which hitherto have been considered as affections acquired in postnatal life owing to purely functional or functional-osteopathic conditions. It seems to be the etiological factor of habitual lateral sclerosis, which may more rightfully be called delayed congenital sclerosis or sclerosis congenitalis tarda. The author goes on to show that congenital deformities need not show directly after birth. Deviations from the normal numerical divisions of the vertebræ may vary in a cranial or caudal direction. The female spine has a marked tendency to vary in a cranial, while the male spine has a marked tendency to vary in a caudal direction. In general the left side of the spine has a strong inclination to vary in a cranial and the right side in a caudal direction. Cranial and caudal variations in this sense refer to the fact that the regional boundaries of the spine are placed respectively higher or lower than normal.

Exploratory Puncture of the Pericardium.—Three cases are reported by G. C. Seare. In all the needle was first introduced in either the fifth or sixth left space in the neighborhood of the anterior axillary line, and then pushed inward toward the heart until fluid was obtained. In the first this site was chosen because a soft friction sound could be distinctly heard over the whole precordium, as if the heart was close to the anterior chest wall and therefore in danger of being wounded if the needle were inserted near the sternum. The selection of the same route in the second was chiefly determined by the success of the previous day. In the third there was added reason for adopting it, yet the author confesses to a feeling of greater confidence when introducing the needle at this point than when it is plunged in directly over the heart, which the experience of surgeons, who have found that the heart not infrequently lies close to the anterior chest wall, when the pericardium is opened to secure permanent drainage, has shown to be reasonable. Indications for operation are large pericardial effusions in spite of treatment, the failing strength of the patient in consequence of the effusion, and danger to life from extreme dyspnea. Pathologically the condition is analogous to that of pleural effusion, but not therapeutically, for we can limit pleural adhesions by restricting chest movement, but we cannot regulate the movements of the heart. The author claims that pericardial aspiration has been shown to be a reasonably safe procedure and in desperate cases it is less dangerous than to submit the patient to a much longer and severer operation, while the relief furnished, even if temporary, may place him in better condition to undergo more radical treatment. Even under the restricted use which has thus far been made of it, it has proved itself a valuable means of diagnosis, of palliation, and often of cure, but where aspiration fails or where the fluid repeatedly reaccumulates and the underlying condition is not incurable, or where there is a strong probability of pus, a permanent opening should be favorably considered.

New York Medical Journal, November 24, 1906.

The Prevention of Epididymitis.—W. T. Belfield reviews the various attempts which have been made to prevent the spread of gonorrheal infections to the epididymis and reports six successful personal cases. He thus describes his operative procedure. The vas deferens is held by the fingers against the skin of the scrotum near the median line, while a half curved needle is passed through the skin under the vas. A half-inch incision exposes the vas; a transverse or longitudinal incision into the vas opens its canal. The blunted needle (curved) of a hypodermic syringe can be passed into this minute canal, and a watery solution of any chosen agent injected; this liquid traverses the vas and ampulla, and enters the seminal vesicle. A fine silkworm gut suture is passed into the lumen of the canal at each extremity of the incision and out through the wall of the vas a quarter inch or more distant; one suture end is then passed through the skin and the two ends tied loosely outside. This suture, entering the lumen of the proximal end, serves to guide the needle when daily injections are to be made. When complete transverse section of the vas is made, the suture arrangement is identical with that described for the fistula formation. When the incision into the vas is longitudinal an additional suture (catgut) is passed through the edges and tied loosely above the skin. This operation is done under local anesthesia in the office, the patient walking away at its conclusion and losing no time from his vocation. When restoration of the canal is desired, the silkworm suture is tightened so as to appose the cut ends; when the wound is healed the suture is removed. Restoration of the lumen of an occluded vas is accomplished by excising the occluded portion and suturing the divided ends in the same way; the lumen of the vas is maintained during healing by the thread within it.

Etiology of Gastric Ulcer.—M. R. Baker does not believe that the etiological basis in this condition can be logically founded on the theories either of blood stasis or infection. The real etiology may be classified as remote and immediate. The former comprises all those influences which cause an oversecretion of hydrochloric acid by the cells in the gastric glands. These influences are numerous and varied, and perhaps cannot be definitely determined in a given case. The latter comprises the following elements: An excess in the amount of free HCl for an indefinite time in the gastric juice with resulting faulty digestion in the stomach and trauma of the pyloric mucosa due to the forcing of undigested masses through the narrow outlet for a long period of time. This combination of forces overcomes nature in a certain percentage of cases, and ulcer results. Anemic patients are particularly susceptible to those influences which produce oversecretion of hydrochloric acid in the gastric cells. Hyperchlorhydria often complicates this condition, and frequently terminates in gastric ulcer on account of the devitalized condition of the general system.

The Insanity of Adolescence.—An elaborate paper on this topic is presented by C. C. Beling, who appends statistics taken from the Morris Plains (N. J.) Asylum. He discusses the question under the headings of etiology, premonitory symptoms, clinical forms, and characteristics, prognosis, diagnosis, pathology, and treatment. Under the head of diagnosis he enumerates as the invariable and fundamental features of the disease, a loss of mental activity and of interest in general, the failure of every impulse to energy, and a weakness of judgment. All other symptoms are merely transitory features, though they may be prominent in individual cases. This statement refers particularly to delusions, hallucinations, and fluctuation of spirits. Definite recognition must be given to the factors of age, heredity, and the premonitory symptoms. One of the most important of these is a weakening of the power of attention, or it may be a disinclination or indifference on the part of the patient resulting in the nonexercise of attention. There may be more or less marked mental fatigue induced, which has the effect of producing a failure to accomplish work undertaken. This condition often leads sooner or later to an abandonment of all mental efforts, and a feeling of apathy which is often mistaken for depression. These symptoms are scarcely noticed by parents and friends, or even by the family physician, as being the precursors of mental disease. They are often obscured by superadded symptoms of a more or less neurasthenic character. Headaches are complained of, sleeplessness is frequently developed, and irritable and capricious moods are often manifested. Along with these symptoms there may be a degree of conduct and behavior so sensible and properly directed as to further mislead one as to the developing mental derangement. In discussing the matter of treatment the author says that all such cases should be sent to insane hospitals and kept under constant supervision. A certain amount of liberty may be allowed. Bone and fat should be built up by diet and the proper medicinal foods. Too much flesh and nitrogenous food should be avoided during growth and adolescence. A strict ban should be placed on alcohol and nervine stimulants. Orderliness and method must be insisted on in all things. The author feels that a particularly urgent duty rests on the family physician who gets to know all the foibles of the various members of the family; he is told collateral history of the family diseases, weaknesses, and habits. In fact, he learns much about the hereditary defects of all its branches; he observes the various tendencies of the

children, some of them exhibiting precocious proclivities, and others manifesting a retiring disposition. The matter of their schooling is often referred to him, and at various times he has the opportunity of learning as to the progress they have made in their studies. To him, therefore, must we look for interest and cooperation in our study of the insanities of adolescence.

A Hemolytic Agent Obtained from the Urine in Pernicious Anemia.—G. W. McCaskey reports one case occurring in a man of thirty-five years with a progressive debility and anemia of unknown origin and an indefinite beginning. The blood examination showed hemoglobin 25 per cent., red cells 950,000 per c.m., giving a color index of about 1.25. Megaloblasts were found and poikilocytosis was well marked. The white cells were 5,000 per c.m., and were histologically normal in the stained slide. The analysis of the urine gave the following results: Total quantity for twenty-four hours, 1,800 c.c., no albumin or sugar; total urea excretion, 20 grams; chlorides, 2 grams; no bile pigments, a trace of indican, a large amount of phenol, and a [illegible] demonstrated after distillation. Microscopical examination entirely negative. Purin bodies, 378 milligrams. This amount of purin bodies, exclusive of uric acid, was many times larger than the author had ever found before and suggested to him a possible relationship to the anemia. He made elaborate analyses to isolate these bodies, and his tests showed a slow destructive action on the blood cells of some body or bodies of the purin group. The precise nature of the chemical substance producing this effect cannot at the present time be demonstrated. All the author claims is that in the present case of typical pernicious anemia there was, first, an extraordinarily large amount of the xanthin bases, or at least of bodies resembling them by being precipitable by silver nitrate; and second, that these bodies removed from the urine of that case, and held in a one-twentieth of one per cent. solution made isotonic for blood exerted a positive but slow destructive effect *in vitro* on normal erythrocytes.

Journal of the American Medical Association, December 1, 1906.

Excision of Cancer of Head and Neck.—G. Crile says that cancer of the head and neck is fatal only by direct extension and not by secondary foci in distant organs, and points out the essentials of the surgical treatment in this region, especially the necessity of complete and thorough operation. He urges the necessity of guarding against infection by isolating the mouth and air passages and controlling hemorrhage by temporary closure of the external carotid, following the details as described by him in former articles, and which are here repeated. He calls attention to the fact that in his own operative cases, 132 in number, out of forty-eight traced patients operated on by him over three years ago and in which the radical block dissection was not made, nine are living, while of the twelve in whom this method was practised, also nine are still living, thus showing that the radical block method is four times as life saving as the less radical one. His general conclusions are "that, since the head and neck present an exposed field, cancer here, unlike that of the stomach, the intestines, or even the breast, may be recognized at its very beginning; that every case is at some time curable by complete excision; that the field of regional metastasis is exceptionally accessible; that cancer rarely penetrates the extraordinary lymphatic collar of the neck; that the growth tends here to remain localized; that by applying the same comprehensive block dissection as in the radical cure of breast cancer and by freely utilizing the modern researches of surgery the final outcome in cases of cancer of the neck and head should yield better results than that of almost any other portion of the body."

The Role of Nuclein.—G. W. McCaskey gives the results of the examination of 129 cases, with special reference to the uric acid and phosphorus excretion, both derivatives of the nucleins of the tissues, and discusses the part played by the latter in the animal economy. He mentions their resistance to the gastric fluids and remarks that if they are finally proved to be indigestible the only possible source of nucleoproteids would be a synthesis from other proteids, which is strongly suggested by certain facts, such as the increase in size of the salmon's ovary during its migration, apparently at the expense of its muscular tissues. It is also probable that the nucleoproteids of the blood serum aid in bacteriolysis, and that phagocytosis itself may be a phenomenon of the leucocyte. Thus their bactericidal effect may be a protective. The toxic character of some of the products of nuclein disintegration is fairly well established, and it is suspected on clinical grounds that some of these may be the cause of certain types of aseptic fever. Uric acid is not included in these toxic products, and the purin bodies are much more important from a clinical point of view than the uric-acid excretion itself. We should recollect as regards these points, too, he says, that there are individual as well as specific and generic variations in the output, in which the uric-acid output may be taken as an imperfect index. McCaskey notices especially the peculiarities of his findings in Bright's disease, the average excretion of uric acid being large, something over one gram, and the small amount in diabetes, a condition which is not readily explainable.

Lactic Acid in Metabolism.—A. R. Mandel and G. Lusk have studied the part played by lactic acid in general metabolism, experiments having been made on dogs. They find that dilactic acid given to a phlorizinized dog may be completely converted into dextrose, while l-lactic acid may be in part so converted, and may in part burn within the organism. As dextrose is the sugar of the blood, so d-lactic acid is the acid found, and is present in all normal tissues, and in increased quantities in arsenic and phosphorus poisoning. That lactic acid is produced from dextrose in metabolism is shown by the experiments of Embden, and it is evident that the sequence may be given as follows: Lactic acid, dextrose, glycogen, dextrose, lactic acid. The metabolic conditions of phosphorus poisoning as regards the part played by lactic acid are discussed. The paper is decidedly a technical one.

Multiple Neuromata of the Skin.—W. E. Darnall reports three cases in men aged nineteen, twenty-two, and thirty-three respectively. One was a clerk in an office, one a clothing cutter, and the third a farmer. In the first case two of the tumors were excised under cocaine anesthesia, and microscopical examination showed them to be neurofibromata. In the second case the patient died from exhaustion caused by a large and painful sarcoma in the course of the sciatic nerve. A hip-joint amputation was considered, but the patient succumbed before any radical treatment could be instituted. In the third case the tumors were present on the front of the left elbow, between the first and second toes of the right foot and on the legs. There was muscular weakness of arms and legs. In this case a diagnosis was made of neurofibromatosis, probably with pressure on the cord by tumor of the nerve roots.

Aperients and Peristalsis.—F. Pfaff and L. Nelson have observed the effects of drugs on the phenomena of peristalsis in the stomach and intestines, exposed in salt solution in such a way that respiration of the animals was not embarrassed. Well-fed cats and rabbits were used. In their preliminary observations of the normal action of the viscera under the stimulus of food, the most striking feature was complete irregularity in the action of the intestines; the so-called segmentation of intestinal contents, which in the last eight years has been described as a normal function of the intestinal peristalsis, was not once observed. They also repeated Cannon's experiments with the *x*-ray, in which, however, only the coarser movement could be followed, and not the finer working of the intestines. Both methods, they think, affected the normal condition of the animal to some extent; the saline solution may act as a stimulant to peristalsis, but the factor which produced the same results in the case of the *x*-ray could not be stated *a priori*. It is certain that some drugs used in both methods acted as aperients, whereas the same drugs were without effect in the control animals. Of the drugs used, croton oil, aloes, and podyophyllin increased markedly the peristalsis of the whole gastrointestinal tract. The stomach peristalsis was much intensified. With aloes, the peristaltic waves began high in the fundus of the stomach and made very deep constrictions. Their number was decreased, but in spite of this the organ emptied itself with great rapidity. Scammony, gamboge, elaterium, jalap, euonymin, and frangula increased very slightly the gastric peristalsis, but markedly that of the large and small intestines both in the salt solution and the *x*-ray experiments. With scammony and gamboge there was, besides increased peristalsis, diarrheic defecation, most marked in the *x*-ray experiments, which was lacking in the control animals. Cascara increased intestinal peristalsis, and also caused defecation under the *x*-ray. Tincture of rhubarb gave negative results, but the infusion increased peristalsis and caused nondiarrheic defecation. Strong solutions of senna increased peristalsis and

caused defecation with both *x*-ray and saline bath. Purgation gave no results, even when the dose was increased, so far as to cause nephritis. Of the salts, sodium sulphate increased peristalsis and caused watery discharges in all the animals experimented on, including the controls. Sodium phosphate acted similarly, but did not increase the gastric peristalsis so much. Sodium chloride was negative in small doses; in larger ones it caused a toxic gastritis. Nux vomica did not increase peristalsis in either rabbits or cats under the *x*-ray or in the saline solution, and control animals also gave negative results as regards defecation. The authors suggest a hope from these experiments that aloes, podophyllin, and the salts may be of value in atonic conditions of the stomach.

Insomnia.—J. T. Fisher discusses the treatment of insomnia by mental suggestion and reports three cases thus treated. Drugs and physical treatment, he thinks, are unreliable for a permanent cure; they may give temporary relief, but continued dependence on them has a bad effect, and tends to render the condition chronic. Even such simple matters as a hot foot bath or a warm drink on retiring, if continued, produce a bad habit and a dependence on them by the patient, which in a measure seems to lessen the effect of direct suggestion. In two of his cases this last was all that was used. The patients were told that they would sleep, and relieved of needless fears about their condition. In the third case posthypnotic suggestion was employed. Any treatment that leaves out this suggestive factor must be a failure. Most insomnias are distinctly of mental origin, and their successful treatment must be through avenues directed to overcoming false ideas and replacing fear with healthful quieting thought, together with the removal of irritants which directly or indirectly affect the minds of the patients.

The Journal of Nervous and Mental Disease, November, 1906.

Chronic Intussusception with Complete Inversion of the Appendix.—Case report by Jas. Struthers. The patient was a poorly-developed girl of five years, with attacks of abdominal pain and diarrhea dating back two months. Later vomiting was added, and protrusion of bowel from the anus. When admitted to the hospital immediate operation was considered advisable. Abdominal incision was made through the left rectus muscle near the middle line. The descending colon at once presented moderately distended by the intussusceptum but not apparently otherwise affected. Two fingers of one hand were passed into the pelvis and reached below the apex of the intussusceptum in the rectum without difficulty. By moderate pressure the intussusceptum was gradually made to travel back along the descending, transverse, and ascending colon, which were successively brought out at the wound, an unusually long ascending and descending mesocolon making this easy. No adhesions had formed between the opposing peritoneal surfaces, and the wall of the intestine was only slightly thickened in the region of the cecum and ascending colon. Reduction was consequently easy, and when the ileocecal junction and the cecum finally appeared it was thought that reduction was complete. On inspecting the cecum, however, it was found that there was apparently no appendix and the site where it should have arisen was marked by a dimple in the cecal wall. Palpation then revealed the fact that the appendix was projecting into the cecum. After one or two ineffectual attempts to express it, the cecum was packed round with gauze, [illegible] aspect, and the appendix at once found projecting into its interior and completely inverted. It was amputated at the base, the edges of the mucous membrane at its origin were united by a silk stitch, and the incision in the cecum was closed by a double row of stitches in the usual way. The abdominal wound was then closed, no drainage being employed. The child's condition at the end of the operation appeared little worse than at the beginning. There was no vomiting after the operation and the child made an excellent recovery. She was discharged from hospital in good health five weeks after admission.

Delayed Chloroform Poisoning.—Three fatal cases are reported by E. D. Telford and J. L. Falconer, who make a clinical study of the subject and find that there are more than seventy cases on record. Of this number but thirty cases are recorded with sufficient detail to permit of careful analysis. In the majority of these the symptoms have developed within thirty-six hours. The symptoms common to all of them are the following: Vomiting often severe and continuous is present, the vomitus resembling "beef tea" or "coffee grounds." The patient may be drowsy, listless, and apathetic, and this condition may deepen into coma before death. In some instances a preliminary stage of restless excitement or of delirium is seen. The pulse rate is quickened and toward the end is running and beyond count. The temperature is sometimes normal, sometimes very high just before death. Air hunger, acetone in the breath and urine, and some degree of cyanosis are usually present. In the majority of cases the symptoms terminate within three or four days from the administration of the anesthetic. On post-mortem examination the most striking and constant feature is the fatty degeneration of the liver. This degeneration of the liver is usually so marked that some writers have described the color of the organ as "canary yellow." Fatty degeneration is also seen in the heart, the kidneys, and often in the gastric mucosa, while in other cases these organs are the seat of cloudy degenerative changes. These represent the constant and essential lesions. Analysis of the entire group of cases suggests that the cause of death is analagous to that acting in acid intoxication. The authors formulate the following propositions: (1) Chloroform, ether, and ethyl chloride may produce a temporary aciduria; (2) so far as is shown by the ordinary routine clinical tests this aciduria occurs not invariably, but in the vast majority of cases; (3) ethyl chloride, either when given alone or when used as an introduction to chloroform, does not appear to differ from other anesthetics as regards the post-anesthetic aciduria; (4) there is no relation between the duration of the aciduria and the length of time during which the anesthetic is administered; (5) the acid bodies occur frequently in the urine of patients in apparently normal health and general anesthesia appears to have no special prejudicial action in these cases; and (6) the change of diet involved in preparation for a surgical procedure does not appear to produce aciduria.

British Medical Journal, November 17, 1906.

Abortion Following the Use of Diachylon.—F. W. Hope Robeson reports the case of a married woman who, believing herself pregnant, took some pills recommended by a neighbor. Two were taken night and morning for three days, with a three-days interval. She took the pills for about a fortnight, but on a few occasions increased the dose, taking three pills night and morning. When she began to take the pills she had amenorrhea; but after a fortnight had a miscarriage. This cleared up in a few days, and she remained regular for about six months, when she had a second miscarriage, the fetus in this instance being about two months old. When seen three months later she was found to be suffering from pelvic peritonitis. She stated that though she took diachylon pills as above [illegible] count of having seen her periods regularly, she was not aware that she was pregnant when the second miscarriage occurred. The typical blue line on the gums was still quite distinctly visible. The interest of the case is that the patient, after having taken diachylon for a fortnight, aborted twice, the second abortion occurring five months after having taken the pills.

Suprapubic Lithotomy with Enucleation of the Prostate in an Aged Patient: Recovery.—H. Littlewood's patient was ninety years of age. The case presented no unusual features. Chloroform was used and the bladder was opened without the employment of any distending fluid. The prostate was enucleated in one mass and with it a portion of the urethra; the resulting cavity and bladder were packed with long strips of gauze. The urine drained freely through the latter without any collecting on the bladder. Packing was removed in three days. The man made a good recovery from the operation. He lived two years, and finally died of uremic coma.

Self-Restraint in Surgery.—Basil Hall deplores the prevailing tendency to hasty operation. It arises from two widely different impulses. On the one hand the timid surgeon is driven to premature and perhaps unnecessary interference by his fears of the possibilities present or to come. He argues with much plausibility that it is "better to be on the safe side," and that the consequences of unnecessary operation are as nothing when compared with the possible dangers of delay. "When in doubt, operate," is the modern surgical axiom; and, while we must all agree that it is sound as a general rule, its influence insidiously extends beyond reasonable limits, and cannot, therefore, be too carefully guarded against. On the other hand, to the

surgeon of large experience, resort to operation comes easily, especially in hospital practice, where the possibility of catastrophe is reduced to a minimum by the facilities afforded for perfect technique. Probably he has arrived at that stage of his career when he has little opportunity to study ultimate results, and consequently he only infrequently realizes that immediate success has been obtained at the cost of more or less permanent disability. The present tendency is doubtless a reaction from the consequences of too long delay in operating in time past, but the pendulum has swung too far. One of the worst effects of this hasty resort to operation is the tendency to neglect clinical observation and shirk accurate diagnosis. The consequence is that the modern surgeon while shining brilliantly in the environment of an operative major case is often "stumped" in the presence of a nonoperative surgical lesion, and really does not know what to do. The case bores him and he hints that it ought to be transferred to a physician. He can operate so well that he is not properly careful in the saving of injured parts and their restoration to proper function. He forgets the old maxim that "amputation is the reproach of surgery." Operations are done because it is the fashion to do them. In the days—not so long past—when almost every wound suppurated, and when the rate of mortality after operation was high, the knife was often more, or more immediately, dangerous than the malady against which it might be directed. But now it has become so efficient and so safe a remedy that the temptation is strong to resort to it, to the neglect of other means which are slower, even if equally efficient, and even to facilitate diagnosis. To much of this no objection can be made. The objection is in the careless, hasty, inconsiderate or self-interested application.

Operative Treatment of Ulcer of the Stomach and Its Chief Complications.—This topic receives a thorough though condensed consideration by Mayo Robson. He advances the following arguments in favor of gastroenterostomy in the condition referred to: (1) Other ulcers present at the time of perforation will probably be cured by the operation. (2) If a second ulcer is on the point of perforation such perforation will probably be prevented, as tension and pressure on the stomach walls will be avoided. (3) After gastroenterostomy more secure healing of the sutured ulcer is likely to occur, and there will be less likelihood of the stitches giving way. (4) It diminishes the risk of hematemesis occurring after operation. (5) It enables saline aperients to be given shortly after operation, and so secures more efficient drainage of the peritoneal cavity. (6) It permits earlier feeding than would otherwise be the case had no gastroenterostomy been done. On all these accounts, therefore, it is important that, where the patient's condition will permit of it, the question of the performance of a gastroenterostomy should be seriously considered at the same time that the perforating gastric ulcer is closed. Concerning hemorrhage at the time of operation Robson notes that he has operated on four cases of acute hematemesis during the continuance of the bleeding. All the patients recovered and remain well. He has also operated between the attacks on twenty-two patients suffering from hematemesis due to ulcer; in all a gastroenterostomy was performed, with recovery from operation in twenty-one. In one case death occurred at the end of a week from exhaustion. He lays down the following propositions for guidance in case of this particular complication: (1) In a case of acute hematemesis from ulcer or erosion when the onset of bleeding is sudden and the previous history of ulcer is absent, medical and general means should be very thoroughly tried, and if the bleeding ceases as the result of rest and general treatment, there will be no cause to interfere surgically, though treatment should be carried out thoroughly and persistently until the ulcer has healed. (2) In case of recurrence of bleeding, or if the bleeding persists despite treatment, surgical measures are called for. (3) In case of bleeding from a chronic ulcer, whether the bleeding be slight or severe, surgical treatment is demanded, not only for the arrest of hemorrhage, but also for the curative treatment of the ulcer itself.

Berliner klinische Wochenschrift, November 12, 1906.

Plastic Induration of the Penis and Dupuytren's Contraction.—Neumark says that it has been frequently asserted that there is a connection between plastic induration of the penis and gout. He reports a case in which the penile affection was associated with contraction of the palmar fascia and considers that this combination affords corroboration of the view that Dupuytren's contraction is also a gouty manifestation. This patient had previously suffered from gouty attacks, although when seen by the author no gouty lesions were present.

The Value of Sahli's Desmoid Reaction.—Aldor reviews the work of those observers who have tested Sahli's desmoid method for determining the functional efficiency of the gastric juice, and then describes experiments of his own made with artificial gastric juice, and in twenty-five cases of different sorts of gastric disorders. He concludes that the desmoid reaction is not a reliable test for free hydrochloric acid, but that it is to be regarded as an index of the general proteolytic power of the stomach, and that it gives only very general information in regard to the digestive power of the gastric secretion. If the reaction is negative it is permissible only to draw the conclusion that there is something amiss with the gastric digestion, but it is not possible to particularize in regard to the details of the disorder. He also expresses the opinion that the universal resort to Sahli's method would in time lead to neglect of the macroscopical and microscopical examination of the gastric contents, which in view of the recent work on occult hemorrhage would be a decided step backward. He believes that Ewald's method will continue to be the most satisfactory for ordinary use, and that Sahli's procedure should be reserved for those cases in which it is undesirable to pass the stomach tube.

Munchener medizinische Wochenschrift, November 13, 1906.

The Aërobic Cultivation of So-called Obligate Anaërobes.—Harrass says that since Tarozzi and Wrzosek have shown that it is possible to cultivate in the presence of oxygen a number of organisms which have heretofore been considered as being strictly anaërobic, he has occupied himself with the question of devising a suitable medium for the routine cultivation of such bacteria. The before-mentioned authors obtained their results by adding to broth a small piece of a sterile animal organ, such as the liver, kidney, spleen, lymph gland, etc., the mere presence of these tissues appearing to be sufficient to enable growth to take place. The author describes the following as being a medium that is not difficult to prepare and which can be kept on hand indefinitely without impairment of its peculiar properties. One pound of fresh calf's liver or calf's brain is chopped up in a sausage machine and is added to a liter of water (sometimes together with 1 per cent. of peptone or glucose, though this is not necessary) is neutralized and is then, after shaking thoroughly, put into sterilized Erlenmeyer's flasks. These are plugged with cotton and sterilized in live steam for one and one-half to two hours. For use, about ten c.c. of the fluid and sediment are poured into a test tube and inoculated. In every case the author obtained by the use of this medium a vigorous growth of the anaërobic organisms. The effort to devise a solid culture medium to facilitate the identification of aërobes in mixtures has so far been unsuccessful, but the author hopes to be able to discover such a medium also.

Deutsche medizinische Wochenschrift, November 15, 1906.

Studies on the Permeability for Bacteria of the Gastrointestinal Canal.—Uffenheimer believes that it has not yet been demonstrated beyond all cavil that tubercle bacilli pass through the wall of the gastrointestinal tract and reach the lungs through the blood or lymphatic stream. The experiments of Schlossmann and Engel appeared to be conclusive, for in order to avoid any possibility of having the organisms travel directly to the lung from the pharynx these observers injected the tubercle bacilli into the stomach through a laparotomy wound instead of introducing them into the body through the mouth and esophagus. The author describes an extensive series of experiments by means of which he was able to show that a test organism such as *Bacillus prodigiosus* injected into the rectum very promptly makes its way into the stomach and into the lungs. If, however, the esophagus is divided between two ligatures before the bacterial enema is given the bacilli do not reach the lungs, and the author considers that this fact that minute particles can travel rapidly over mucous surfaces in a direction opposite to the peristaltic motion must be considered in all experiments of this sort. He therefore concludes that Schlossmann and Engel's results are fallacious since this possibility was not taken into account in their work.

Book Reviews.

KLINIK DER BRUSTKRANKHEITEN. Von Dr. med. ALFRED v. SOKOLOWSKI. In two volumes. Berlin: August Hirschwald, 1906.

THE present work originally appeared in Polish and has been translated by Fabian into German, thus presenting this excellent treatise to a larger audience. Sokolowski was for many years associated with the celebrated Dr. Brehmer at his sanatorium in Görbersdorf and then achieved prominence as a clinician in one of the largest hospitals in Warsaw. The book is intended to serve as a practical manual, and theoretical discussion is entirely omitted from the text except in so far as it is needed to illustrate the subject. Considerable space has therefore been given to etiology and clinical history, as well as to therapeutics and prophylaxis, while pathological anatomy, histology, bacteriology, and similar subjects are treated only [illegible].

The four parts of the book deal with diseases of the trachea and bronchi, the lungs, the diaphragm, and tuberculosis, and as the writer's clinical experience has been enormous, a large amount of original work and ideas are presented which cannot be reviewed within the limits of this note. Polish literature, which has thus far been largely inaccessible, is freely drawn upon and thus becomes available for the general reader; but the writer's bibliography also includes references to the medical literature of all other nations. An enormous amount of material is presented and no affections of the thorax, no matter how rare and infrequent, have been omitted. A word of commendation must also be said for the translator who has done his work, usually a thankless task, in a most worthy manner, and the text reads as if it had been originally written in German. The book is well printed, but contains no illustrations whatever, which in some respects is a relief. Monumental is the term which will best describe the work.

THE PHYSICIAN'S VISITING LIST (Lindsay & Blakiston's) for 1907. Fifty-sixth Year of Its Publication. Philadelphia: P. Blakiston's Son & Co.

THIS well-known visiting list makes its appearance promptly, so that those who have always used it may secure a new copy on hand when the new year begins, and those who are beginning and have to decide what visiting list to adopt may have time to examine the different lists in the market before making their choice. In addition to the blank leaves for the visiting list, memoranda, addresses, obstetric engagements, cash account, etc., there are the usual tables of doses, incompatibility, signs, poisoning, a complete table for calculating the period of uterogestation. The paper, printing, and binding are all excellent.

ATLAS OF CUTANEOUS MORBID HISTOLOGY. Consisting of Fifty-three Colored Figures on Twenty-four Plates, and Text. By Dr. MAX JOSEPH, Physician for Skin Diseases in Berlin, and J. B. VAN DEVENTER, Oberstabsarzt of the Netherlands East Indian Army in Batavia, Java. Chicago: W. T. Keener & Co., 1906.

THE interesting and important field of the minute pathology of skin lesions is usually treated in somewhat stepmotherly fashion, both in works on pathology and in those on skin diseases. The present collection of plates comprises a very instructive series of depictions of microscopical sections of most of the common disorders of the integument and should do much to compensate for this omission. The text is concise but adequate, and the drawings have been carefully drawn and well reproduced, so that the atlas should prove of much interest and practical value to any medical man who is ever called upon to treat cutaneous disorders—and what practitioner is not?

APPLIED BACTERIOLOGY. An Elementary Handbook for the Use of Students of Hygiene, Medical Officers of Health, and Analysts. Revised and Edited by CRESACRE G. MOOR, M.A., Cantab., F.I.C. Formerly Public Analyst for Exeter and Senior Demonstrator in Public Health, King's College, London. With the Cooperation of RICHARD TANNER HEWLETT, M.D., F.R.C.P., D.P.H., Professor of Bacteriology, King's College, London, Formerly Bacteriologist to the Lister Institute. Third Edition. New York: William Wood & Co., 1906.

BACTERIOLOGY is so progressive a science that it is difficult for the ordinary reader to keep pace with its advances. Almost each month sees some discovery or new point of view put forward that sometimes is only of academic interest, but more often has such far-reaching practical application that it behooves the practitioner who would do his duty by himself and his patients to let no opportunity pass by for keeping his knowledge abreast of the times. The present volume is well adapted to serve the purpose of restoring to the memory details once known, but since forgotten, and of providing a complete, well-written summary of the newer knowledge that is the fruit of the investigations of recent years. The text is succinct but clear and thoroughly modern, as is shown by the inclusion of topics of such recent development as the ultramicroscope of Siedentopf and the *Spirochæta pallida* in syphilis. The recent theories of immunity are concisely set forth, though the section on Ehrlich's complex hypothesis suffers somewhat through the absence of explanatory diagrams. The latter portion of the volume is devoted to the practically important subjects of disinfection and disinfectants, particularly as applied to the disinfection of houses, and the examination of milk and water. For all but the most advanced workers the volume may warmly be commended as a thoroughly satisfactory exposition of the bacteriology of to-day, particularly as it concerns the practitioner.

A TEXTBOOK OF GENITOURINARY DISEASES, Including Functional Sexual Disorders in Man. By Dr. LEOPOLD CASPER, Professor in the University of Berlin. Translated and Edited with Additions by CHARLES W. BONNEY, B.L., M.D., Assistant Demonstrator of Anatomy, Jefferson Medical College, etc. Philadelphia: P. Blakiston's Son & Co., 1906.

THE translator and the publishers of this volume have rendered a commendable service to English-speaking readers in presenting an English version of Casper's textbook, which represents the technique of one who for some years has been regarded as an authority of the greatest eminence in his field. The German edition of this work is now several years old, and the translation has had the benefit of a revision by Dr. Casper, as well as of editorial annotations in brackets by Dr. Bonney.

The book deals purely with genitourinary diseases in man, and does not include a consideration of syphilis, nor of the genitourinary diseases of women. The arrangement of the subject-matter is practically the same as that which we are accustomed to find in the average American textbook on genitourinary diseases. The translation has been done accurately, yet with commendable freedom from Teutonic reminiscences, such as are but too frequently met with in modern medical translations.

The reviewer's test for a practical and up-to-date textbook on genitourinary diseases is: Does the book present a thorough, detailed, practical account of the modern treatment of gonorrhea and its complications, and does it deal in a practical, systematized, lucid, and well-illustrated manner with the treatment of stricture and with the minor operations which are performed by the general practitioner: meatotomy, circumcision, incision for paraphimosis, varicocele and hydrocele operations, and operations for bubo. A knowledge of the functional examination of the kidney is less essential to the general practitioner than the subjects enumerated. He who seeks the corresponding chapters in Casper's volume will be but partly satisfied. Very little is said of the newer silver salts in gonorrhea; the technique of injections and irrigations is but scantily covered. Under the heading of internal urethrotomy the Otis urethrotome, which almost everybody in this country uses, in strictures which permit its use, is not even mentioned; nor are the methods of urethrotomy with divulsion (Otis, Oberlaender, Kollmann *et al.* mentioned. The direct division of strictures in the anterior urethra with Kollmann's knife through the urethroscope is not described. The surgical treatment of hydrocele is fairly well covered, but in discussing operation for varicocele a paragraph is devoted to the subject (page 433) and but scant practical information given. The author is very saving with his words when speaking of circumcision (page 179), but the treatment of bubo is adequately covered (page 191). The chapters on functional disorders will be found very useful.

It has always puzzled the reviewer what such urethroscopic pictures as appear on pages 21-23 are supposed to convey to a reader who is unfamiliar with the appearance of the interior of the urethra, yet similar cuts are printed in many books. The cystoscopic photographs are reproduced after Nitze's beautiful plates, but have been much damaged by the reproduction. Many misprints have crept into the text, *e.g.*: "phosphorous (the drug) three times on pages 588-589; "Kraft-Ebing," page 551; bouillion, page 47; "loose their smoothness," page 47, etc.

A second edition of this translation will, no doubt, give an opportunity for the correction of these minor faults and for fuller editorial annotation. The authority of Casper is such that anything from his pen is bound to be popular; hence attention to these points is all the more desirable. The book as a whole is to be recommended to those who are not able to read German, and who want to have Casper's teachings in accessible form.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Fourth Regular Meeting, held October 12, 1906.

THE PRESIDENT, DR. T. MITCHELL PRUDDEN, IN THE CHAIR.

The Effects of Radium Upon a Dark, Hairy Mole of the Face.—Dr. Robert Abbe presented a young girl with a congenital hairy mole of the left cheek. The lesion originally measured one inch by one and three-quarters. The lower half had been removed by four applications of radium, each lasting one hour, made at intervals of a few days last June. Under the applications of the radium, the long, soft mousy hair rapidly fell out, leaving an atrophic and comparatively insignificant scar. Dr. Abbe said he had shown the patient at this stage to demonstrate both the effects of the treatment and the original appearance of the lesion. In reply to a question, the speaker said that the effects of radium seemed to be most pronounced upon lesions of a hypertrophic character. Thus, he had seen a black, hairy mole, the size of an adult thumb nail, disappear after two applications. He had never tried it in simple hypertrichosis.

Dr. WALTER B. JAMES asked if any ultimate injurious effects had ever resulted from the use of radium? He referred to the observations of Dr. J. Nevins Hyde on the influence of sunlight on superficial epitheliomata, and as the relation between sunlight and radium was moderately close, he inquired whether any tendency to the development of such skin lesions had been shown after applications of the latter agent. He also asked what Dr. Abbe's further experience had been in the treatment of exophthalmic goiter by incision and the insertion of the radium tube.

Dr. ABBE said he had never seen the slightest tendency toward the formation of epitheliomata or other ill-effects from the applications of radium. For the past three years he had carried on his own arm a perfectly healthy radium scar. In reply to Dr. James' question as to his further experience with radium in exophthalmic goiter, Dr. Abbe said that in the first case in which he had resorted to the method, in which the tumor had been an enormous one, the patient had remained perfectly well. The other cases had acted variously. Out of nine in which the method had been employed three had been relieved of their symptoms. The others had improved to some extent. The method should not be regarded as a cure-all in these cases, and the improvement in the symptoms could only be attributed to the diminution in the size of the goiter, which in turn was due to the retrograde effect of the radium upon hypertrophic structures. In one instance this destruction of the tissues was so active and extensive that the patient developed a temperature of 106°. Extensive sloughing of the gland occurred, but the final outcome of the case was favorable.

The Attempt to Use Fresh Air in the Treatment of Other Diseases than Tuberculosis, and Its Physiological Foundation.—Dr. WALTER B. JAMES said he was convinced of the fact that an abundance of fresh air, or, better still, the outdoor treatment, was beneficial not only in pulmonary tuberculosis, tuberculosis of the joints, etc., but also in many other conditions, both acute and chronic. The question of what constituted good and bad air, he said, had been under discussion for a long time, and was still unsettled. The temperature, humidity, and stillness of the air had to be taken into consideration. Among various diseases in which Dr. James had found the outdoor treatment beneficial were puerperal fever, typhoid fever, in which to a certain extent it had taken the place of cold baths, and cerebrospinal meningitis, in which it had a markedly beneficial effect upon the nervous symptoms. This quieting effect of the outdoor treatment had also been noted by the late Dr. Dent and others in the treatment of various forms of insanity. Furthermore, it had come to be regarded as a valuable adjunct in neurasthenia and in many chronic disorders of nutrition, particularly in chronic gastric derangements and in rachitis.

Dr. BEVERLEY ROBINSON said that while he had always endeavored to give his patients as much fresh air as was agreeable and practicable under the conditions in which they lived, he thought the question should be considered from an individual standpoint. There were some patients to whom an unlimited supply of fresh air was disagreeable; there were others who regretted that the windows of the sick chamber were not larger and more numerous. The practical conclusion that he had drawn from his experience and observations was that the quantity of fresh air should be regulated, to a certain extent, according to the susceptibility of the individual, and that a superabundance of fresh air should not be regarded as a cure-all, or even a necessity in the treatment of disease. Of course all agreed that the sick room should be thoroughly ventilated, especially in febrile and pulmonary conditions. Certain patients apparently required an extraordinary amount of covering; others seemed to be comfortable without any covering at all. No hard and fast rule could be laid down in this respect. The pendulum seemed to swing to one extreme, and then to the other. The question was analogous to that of feeding in typhoid fever. It was not very long ago that milk was considered the only form of nourishment that a typhoid fever patient should receive, and the Brand method of reducing the temperature was almost universally in vogue. To-day, in Bellevue Hospital and other institutions, the typhoid fever patients enjoyed the benefit of a considerably more elaborate diet list, and were subjected to fewer cold baths.

Dr. JOSEPH D. BRYANT, after referring to the reluctance he had met with on the part of the house staff to get hospital patients out on the veranda for a certain number of hours each day, said he had become firmly convinced of the fact that surgical as well as medical conditions were improved by fresh air, freely bestowed and properly regulated. He recalled in this connection cases of long-delayed union of the femur in which the fractured ends promptly united under the outdoor treatment. In cases of wounds of the soft parts that were doing badly he had also observed the healing accelerated by exposing the patients to a plentiful supply of fresh air, which unfavorable state might not have happened if anticipated by out-of-door treatment from the outset. The same observation had been made by Halsted and others, and the outdoor treatment of surgical cases in all sorts of weather was long ago in vogue at the Johns Hopkins Hospital. Dr. Bryant said he was scarcely inclined to agree with Dr. James, that a draught was desirable, even in the sick room, and he personally had very distinct recollections of suffering from an incautious exposure to unchecked currents of air.

Dr. EDWARD G. JANEWAY said there was no doubt of the fact that the outdoor treatment of insane patients had reduced the necessity for restraint and drugs. There was also no doubt of the fact that many sick persons were undoubtedly benefited by the outdoor treatment, and there were even many well persons who preferred to sleep out of doors. Personally, Dr. Janeway said he preferred the comforts of a room and bed. The advocacy of a superabundance of fresh air in the treatment of disease, the speaker said, was by no means of recent origin, and he recalled that many years ago, during an epidemic of typhus fever in Bellevue Hospital, many of the patients improved rapidly under the influence of fresh air. In speaking of draughts, Dr. Janeway said there was a popular prejudice against them which it would be difficult to overcome.

Dr. SAMUEL W. LAMBERT, in speaking of the outdoor treatment of puerperal septicemia, to which Dr. James had alluded, said that when the present Lying-in Hospital was located in the old Hamilton Fish house many of the patients were kept out on the veranda and in the garden in

all kinds of weather, and under those conditions an improvement was usually observed even in the severest forms of the disease. In the new building which the society had erected the patients were kept on the roof, and an equal, though no greater, improvement in their condition had been noted. It was the fresh air, apparently, rather than the elevation or the environment, to which the improvement was to be attributed. The speaker agreed with Dr. Janeway that there was a very strong popular prejudice against draughts, and if a sick person was exposed to a draught and experienced a relapse the patient's friends would be fairly certain to attribute it to that cause. The same was true of a rather free diet in typhoid fever. It was very difficult to overcome popular prejudice against both of these agents in cases that turned out badly.

Dr. Robert Abbe thought the outdoor treatment of patients involved two principles: one was the refrigeration of the body, and the other was the free supply of fresh air. By placing a fever patient in the open air we exposed an enormous capillary circulation and drove the blood into the internal organs, where the disease was presumably producing its ravages. The blood stasis of the internal organs thus caused was somewhat analogous to the Bier treatment of tuberculous joints by producing a hyperemic condition of the diseased parts. The increased blood supply undoubtedly gave rise to a more active leucocytosis, and the phagocytic action that followed hastened the normal processes of regeneration. If that theory was true, then it was reasonable to suppose that diverting the circulation from the capillaries into the internal parts would be followed by beneficial results. On the other hand, the benefit resulting from the open-air treatment might be attributable to the increased supply of oxygen.

Dr. John Winters Brannan said that while he would not attempt any scientific explanation of the good effects of a plentiful supply of fresh air, he entertained no doubt of the value of this method of treatment. His own enthusiasm regarding it, which began some years ago, had been much increased by his observations of the cases of tuberculous bone and joint diseases among the children at Sea Breeze, Long Island. Arguing from that standpoint, he had come to the conclusion that if the open-air treatment increased the vital resistance of patients who were suffering from tuberculosis, it was also indicated in other conditions where the vitality of the patient was impaired. At the new Harlem Hospital balcony accommodations had been provided for every patient, and according to the plans of the new Bellevue Hospital each bed had been assigned thirty-four square feet of balcony surface, in addition to the roof garden. In order to provide these outdoor accommodations, Dr. Brannan said, he had some difficulty in overcoming the objections of the architects, who feared that the large balconies would interfere with the architectural beauty of the buildings. At the Gouverneur Hospital, where new balconies had been provided, patients in the acute stage of typhoid fever were kept by Dr. Francis Huber on the balcony all day long. On one balcony he had seen four bed patients with temperatures as high as 103° lying with the sun upon their faces, they having asked to have the awnings raised. On the grounds of the old Fordham Hospital they all said they liked it; a cottage tent had been used for the treatment of the pneumonia patients, and, according to Dr. Dunn, the attending physician, thirty cases had been treated there with much better results than had previously been obtained in the wards. During the following autumn the tent was used for typhoid fever patients, again with excellent results. The attending physicians reported that the patients did not complain of draughts, and never took "cold." In addition to the pneumonia and typhoid fever patients, the tent was also used for the treatment of some cases of influenza, heart disease, and bronchitis.

In speaking of the benefit of the outdoor treatment in surgical conditions, Dr. Brannan said he had recently visited the Corey Hill Hospital, at Brookline, Mass., and the Massachusetts General Hospital, and at both of these institutions the value of an abundance of fresh air as an adjunct in the healing of wounds was fully appreciated. In the latter hospital he was told that surgical patients were moved out on to the open balconies on the fourth day after operation.

Dr. W. Gilman Thompson said the subject brought up for discussion by Dr. James was extremely timely, as so many large hospital projects were under way at the present time. He called attention to the importance of keeping the heating and ventilating systems of hospitals separate, and he referred to one hospital where the chief aim had been to keep the temperature of the wards at 70° F. irrespective of freshness of the air. In order to accomplish this the windows were constructed with lock and key, so that the nurses could not open them, and the air in the rooms was never adequately changed. Not long ago, Dr. Thompson said, we thought all was known about the composition of the air. Since then, however, we had learned that it possessed certain additional chemical and physical properties which influenced the human organism, and which could not be safely disregarded in studying the question of ventilation. In the particular hospital to which he had referred, for example, the only consideration seemed to be the uniform temperature, without regard to the number of patients or attendants or students in the wards, who were polluting the air. The old Bellevue Hospital was probably the most rationally constructed institution of its kind in the city from the standpoint of our present knowledge of the subject. The wards were all provided with good-sized balconies and grounds surrounding them, and it was the only properly ventilated hospital, because it had no so-called "system" of ventilation, and had an independent heating apparatus. Dr. Thompson said that during the past summer he had visited a number of the large modern hospitals in Europe, and had become impressed with the extent with which the fresh air idea had taken hold of our confrères abroad. Most of the new hospitals were built on the pavilion plan, not over two stories high, with plenty of ground surrounding them. The wards were ventilated and heated by systems independent of each other. Many of the windows were of the double casement type, so that they could be opened from the top.

Dr. William M. Polk said he could add his testimony to what had already been said in regard to the efficacy of the fresh-air treatment in patients who had just undergone an operation. During the past year he had been in the habit of placing his post-surgical cases in a room with two large windows, which were kept widely open all the time, irrespective of the weather. The effects of this innovation in the after-treatment of these cases had been excellent.

Dr. James, in closing the discussion, said he fully agreed with Dr. Robinson in regard to the inadvisability of following a uniform method of treatment, and he did not wish to be understood as advocating the rather extreme measures that he had referred to in his paper. They were to a certain extent experimental in his efforts to ascertain whether extreme changes in environment would do good or harm. The speaker said he had for some time urgently advocated the abolition of many of the routine or uniform measures that had been so long in vogue in the treatment of hospital cases, and which he regarded as a great blot on our hospital system. A good many years ago, when a man was taken ill, nothing made any difference, providing he had the right doctor and the right drug. Now we thought everything else made a difference, and the choice of a doctor was comparatively unimportant, providing the latter did his patient no harm. In the hospital we still went on using exactly the same environment for the various kinds of diseases, without reference to the individual indications of each case. In no hospital, so far as he knew, had any rational

or scientific attempt been made to adjust the environment to the needs of the individual patient.

Two Hundred and Fifth Regular Meeting, Held on Friday, November 2, 1906.

The President, Dr. Robert Abbe, in the Chair.

Some Notes on Aix les Bains.—Dr. John Winters Brannan read this paper.

Infection by Tænia Nana, with Specimens.—By Dr. Samuel W. Lambert. The patient was a carpenter, twenty-five years old, a native of Germany, and a resident of Brooklyn for several years. His father died of tuberculosis; otherwise, his family history was negative. His previous history was unimportant. He denied venereal infection; was moderately alcoholic. About two years ago he began to suffer with heaviness in the stomach, which was a constant symptom and apparently had no relation to the taking of food. There was belching of gas after meals, with dizziness, and occasional pain in the back. He was very nervous, and complained of general weakness. There was no history of vomiting. About a year ago he developed a cough, with yellowish-white expectoration; no hemoptysis; no night sweats. His appetite was good; bowels regular. He felt worse in the morning. His heart and lungs were normal. The patient first came under observation at the Vanderbilt Clinic on September 20, 1906. An examination of the stomach contents after a test meal showed hyperacidity, but the physical examination was otherwise negative. Various remedies to control the gastric condition were tried, but on October 2 the patient reported that he was no better, he complained of great hunger, and said that he had observed "white flakes" in his stools. Microscopical examination of his feces showed a large number of ova which were identified as those of tænia nana. He was given a two-drachm dose of male fern, and a subsequent cathartic brought away several stools from which several hundred specimens of tænia nana with numerous ova were recovered. Dr. Lambert said that infection by the tænia nana was comparatively rare. In Bulletin No. 18 of the Hygienic Laboratory, issued by Dr. B. H. Ransom in 1904, one hundred cases in man were collected; of these about twenty-five occurred in the United States, all in the South. The infection was first observed in rats, by Dujardin, in 1845, and six years later in man. It is believed that this tænia is comparatively common in children, especially in Italy. The principal symptoms are diarrhea, gastrointestinal pain, headache, nervousness, and even epileptiform seizures. The symptoms are usually slight, and the diagnosis must usually be made by finding the eggs in the feces. The cure consists in the usual tæniacide male fern, though repeated treatments are sometimes necessary to insure a cure. The prophylaxis consists in excluding the excreta of rats and mice from the food. The infection with these parasites is usually direct without an intermediate host, although it is not certain that some insect may not serve in this capacity. In the regular course of events the egg hatches and forms a cercocyst in the intestinal villi which later breaks through and enters the gut to become an adult worm. The habitat of the tænia nana is the ileum and several thousand such worms may inhabit the same intestinal tract. The worm and the egg are quite characteristic; the egg has circumferential striations in its outer zone, while the ova of the usual tape worms have radial striations. The adult worm is about three-eighths of an inch long and its head has a central group of hooklets and four surrounding suckers. In reply to a question, Dr. Lambert said there was no increase in the proportion of eosinophile cells in the case which he had reported.

A Case of Bronchitis, with Remarks on Cough and the Perforated Zinc Inhaler.—By Dr. Beverley Robinson. (See page 900.)

Dr. Brannan said that a few years ago his attention had been called to the perforated zinc inhaler by Dr. Kinnicutt, and he had given it a trial in a number of cases, with very satisfactory results. The inhaling fluid he employed was a mixture which contained, among other things, the compound tincture of iodine. The speaker said he did not know whether creosote had any specific effect upon the class of cases mentioned by Dr. Robinson, but the inhalations certainly seemed to relieve the cough.

Dr. James said that Dr. Robinson's paper was particularly timely, as the type of acute pulmonary trouble to which he had called attention was unusually frequent at this time. In quite a number of cases that had come under his observation recently it was difficult to decide whether the patient had a bronchopneumonia or a simple bronchitis, and the relief of the symptoms was especially indicated. The speaker said he had an impression that the mixture mentioned by Dr. Robinson was of distinct value in this particular class of cases.

Dr. Charles L. Dana said he could recall the time when the inhaler described by Dr. Robinson was used in the wards of Bellevue Hospital with good results in a symptomatic way.

A Case of Supposed Glioma of the Eyeball.—Reported by Dr. Charles Stedman Bull, with specimen. The patient was a girl two years old, who came under observation on November 20, 1905. She was well developed for her age, but anemic, with a pasty complexion, which was in strong contrast to her black hair and eyes, and well-marked eyebrows. The child had always been well until the latter part of September, 1905, when she had an illness lasting about three weeks, accompanied by high fever, and at times by spasmodic contractions of all four extremities. During her recovery the mother noticed that the left eye was red and inflamed, and that a yellow reflex came from the pupil. On examination there was a marked ciliary injection, and a very shallow anterior chamber, the iris bulging toward the cornea, especially at the periphery. The pupil was moderately dilated, and the iris very sluggish. The tension was T-1. The lens was clear, and the fundus was best seen with a sph. + D.12. There was a distinct yellowish reflex from the fundus, over which vessels could be seen passing without the aid of the ophthalmoscope, by oblique illumination. The ophthalmoscopic picture was not entirely that of glioma, though strongly resembling it. The history of the child's illness during the previous September pointed to a possible spinal meningitis. As the eye was painful and showed all the signs of intraocular inflammation, and as the child was distinctly suffering, the parents were advised to consent to the enucleation of the eye, to which they agreed. The diagnosis was somewhat uncertain, and rested between a glioma in the stage of active progression and a suppurative iridochoroiditis due to spinal meningitis. The operation was done on December 20, 1905, and the eye was handed to Dr. George S. Dixon, the pathologist of the New York Eye and Ear Infirmary, who reported as follows: The globe measured 21x21x21mm.; the clear cornea 10.5x11.5mm. When it was divided no anterior chamber was apparent. The depth of the posterior chamber was increased. A cyclitic membrane was present. Projecting from the posterior surface of the lens into the vitreous was a pinkish-white mass, somewhat pyramidal in form, which measured 3 mm. at the base, and 4 mm. in length. Its base corresponded to the middle of the posterior surface of the lens. A similar mass was seen at the disc, projecting toward the anterior pole for a distance of 3 mm. The base of the mass measured 2.5 mm. There was no apparent detachment of the retina. Sections showed the corneal epithelium intact; excepting in one place, and that was probably eroded mechanically, as no infiltration was present. Bowman's membrane was well marked, and the cornea propria normal, excepting that the corpuscles showed a little more distinctly than usual.

Descemet's membrane was practically intact. The iris was atrophied, but contained a comparatively large number of blood-vessels. A synechia anterior, in close contact with Descemet's membrane, was found throughout its extent, with the exception of a small space near the angle. The canal of Schlemm was closed. The posterior chamber was increased in depth, but contained no exudate. The ciliary body was partially disorganized and hyperemic, particularly toward the pars ciliaris retinæ. There was no edema. Many of the ciliary processes were complete, but some were disorganized and passed toward the lens as dense pigmented masses. In the zonular region quite a number of adventitious fibers similar to the suspensory ligament were found, and these carried a number of blood-vessels. The lens itself was not particularly well preserved, but it presented no disorganization excepting near the zonula posteriorly, immediately beneath the capsule. A few of the fibers here showed numerous small vacuoles. The posterior portion of the capsule, especially near the center, was corrugated and thickened. The mass of tissue which was attached to the posterior surface of the lens appeared to be a portion of the dense cyclitic membrane, but it was peculiar in that, in addition to connective tissue and hyaline material, it presented elements of the retina in well-marked folds about the base next the lens, although there was no indication that the retina had been detached to the extent of allowing it to lodge there. The choroid was in position, but atrophied, and small subchoroidal hemorrhages were noted. The nerve was moderately atrophied, and a few small hemorrhages were found in the arachnoid portion of the sheath. The mass at the disc was composed of naked nerve fibers and connective tissue continued forward from the optic nerve, and it enveloped a prolongation of the arteria centralis retinæ. These fibers were surrounded by a double tubular layer of retina. The general macroscopical appearance of the eye at once suggested an error in development, which Dr. Dixon thought was proven by the microscopical findings, although the findings at the disc pointed somewhat to retinitis proliferans. The tissue behind the lens was of such a character as to lead one to suspect glioma on examination before enucleation, but sections dispelled this at once. Macroscopically, there was little indication of retinal detachment in any portion of the globe, and not sufficient to account for its presence at the base of the growth at the posterior portion of the lens.

Dr. Dixon said he was of the opinion that the condition present was primarily and principally due to faulty development, as there was no indication of a very recent or active inflammation in any part of the eye at the time of enucleation. While the illness of the child of which the mother gave a meager history may have resulted in intraocular changes, he thought it much more probable that intrauterine iridocyclitis occurred, which might have interfered with development on the one hand and proper retrogression on the other.

The Action of Quinine on the Auditory Nerve.—Dundas Grant declares that quinine causes congestion of the labyrinth, and also notes that the tinnitus caused by this drug can be quieted by compression on the vertebral arteries. This has the effect of diminishing the pressure in the basilar artery, its branches in the internal auditories, and thereby in the vessels of the labyrinth. This compression may be made in the suboccipital region, the thumb and finger of one hand being placed in the hollows behind the mastoid process, while counter pressure is made by the other hand on the forehead. As the arteries lie under the complexus muscle the pressure must be rather firm. If such pressure checks pulsating noises or vertiginous feelings the inference is that these are due to congestion in regions supplied by the branches of the basilar artery, probably the internal ear.—*Journal of Laryngology.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON DERMATOLOGY.

Stated Meeting, Held October 2, 1906.

DR. A. R. ROBINSON IN THE CHAIR.

Lichen Planus Pemphigoides.—Dr. LAPOWSKI reported this case, occurring in the person of a man, 35 years old, well built and well nourished. Personal and family history negative. Duration of present disease at least ten years. There had been intervals of improvement, but since the trouble began the body had never been entirely free from the lesions. No history of how the process began was obtainable. The patient was first seen early in October, 1905, and the following condition observed: The extensor and flexor surface of both legs were covered with pea to quarter-dollar sized patches of violaceous color and soft consistency. The patches were somewhat raised above the level of the normal skin. Their surfaces were smooth and shiny, with thin adherent scales, like those of lupus erythematosus of the face. In the center of some of the smaller patches there was a bloody crust, while others presented an excoriated center, from which a serous fluid oozed. In either case, the border was slightly infiltrated. All other parts of the body, including the mucous membranes, were normal. In all patches, but especially in the larger ones, the redness disappeared on pressure, leaving a distinct brownish border, corresponding with the size of the patch. The patient complained of intense itching, especially at night. He told of a peculiar sensation of localized tingling, and said that when he scratched such an area a vesicle appeared. I had no opportunity of verifying the statement. A plaster mull of mercury and phenol was applied to the patches for twenty-four hours. When this was removed the patches showed generally three distinct zones: (1) an external dark violaceous border, slightly raised and infiltrated; (2) an inner zone of moist, denuded skin, and (3) an atrophied pale brown center. A week later the centers of some of the patches, both large and small, were occupied by tense serous vesicles and bullæ, from the size of a pinhead to that of a pea. On opening a bulla a serous liquid exuded, and on removing the top a moist reddish surface came to view. Bullæ of the same size and larger appeared on the macroscopically normal skin. Similar patches developed on both wrists and on the region around the axillæ, but not in the parts rich in sweat glands, as in Allen's case. On the dorsal aspects of the feet were pinhead-sized, quadrangular, smooth, shiny, slightly elevated, violaceous papules typical of lichen planus. Asiatic pills were given and the leg was securely bandaged, the patient being directed to have none but the family physician touch it. Under this treatment the bullæ became much smaller and more flaccid, but still continued to appear, both on sites of preexisting and existing lesions and on macroscopically normal skin. After several weeks the patient returned in the following condition: All the raised patches were gone, leaving in their places brownish pigmented areas with depressed center. Neither vesicles nor lichen papules could be seen. The patient considered himself well, when, in May, 1906, the disease reappeared on legs and wrists, but in milder form, and then for the first time lichenoid papules were visible on the glans penis. The mucous membranes and the nails were always free. The urine, examined several times, was normal, and showed neither albuminuria nor phosphaturia. Besides warm baths, the patient was given injections of arsenic by the family physician, alternating with Fowler's solution internally. Then for the first time bleeding from the nose appeared, and the arsenic was stopped. The vesicobullæ did not appear in larger numbers than formerly.

Lichen Planus.—Dr. LAPOWSKI reported the case of a woman, 46 years of age. The present disease, of four weeks standing, started on the lower extremities, spread-

ing over the legs, thighs, and forearms. The neck was first involved a few days ago. The eruption presented characteristic lesions of lichen planus, and the patient was presented for the sole purpose of comparing the lichen papules on her body with the papules in the case just reported.

Tuberculide.—Dr. Lapowski reported this case. The patient was a woman, 56 years of age, married. Both family and personal history negative. Good general health. The present eruption started two years ago, and since that time the patient had never been entirely free from it. At present the whole body was involved, from the face down to the soles of the feet, the eruption consisting of pea-sized tubercles imbedded in the skin and movable with it. The tubercle was hard and painless. The central portion was slightly edematous, whitish, having a pinhead-sized vesicle-like point in the center, but no fluid escaped when the point was pricked. Some efflorescences had a very dark red crust in the center; when the crust was removed a punched-out deep hole with sharp borders and dry floor was seen. The surrounding skin was normal. Such tubercles were scattered over the whole body, but mostly on the lower and upper extremities. Besides these tubercles, there were dark brownish pea-sized spots, and superficial scars over the trunk and extremities. On the soles of both feet dark red penny-sized, irregular, slightly scaly patches were seen. The eruption was very itching, but there were no scratch marks on the body except the dry crusts of the tubercles mentioned before. The eruption began with a sensation of burning and itching; when the patient touched the spot she noticed a hard nodule in the skin which itched very much. The nodule got larger from scratching, reaching the size of a tubercle, remained thus for several days, and then disappeared. Some of them disappeared without leaving any marks; others, even if they did not have a crust, had pigmentary spots and scars. Such nodules might appear in various numbers at different times, sometimes three times in one week on various localities. In the past few weeks the speaker had had the opportunity to see the appearance of dollar-sized patches on the breast, with pale, hard center and, red, inflamed area around it. In forty-eight hours the hardness and redness would disappear, leaving a pea-sized tubercle for six to eight days. But such patches appeared seldom, pea-sized nodules being the rule. The mucous membranes were normal.

Two Epitheliomata on One Lip.—Dr. Lapowski reported the case of a man, 35 years of age, no syphilitic history. He came to the Good Samaritan Dispensary a year ago with an ulceration on his lower lip of several months' duration. The right submaxillary glands were palpable, hard, painless. The patient was given a lotion for local use, and was not seen again for a year. During that time he was treated in a hospital in Philadelphia with caustic applications. About two months ago the second ulcer appeared on the lip. On the right side of the lower lip were two penny-sized ulcerations, the older one nearer the middle, the more recent one nearer the corner of the mouth. The clinical appearance corresponded with that of epithelioma. The speaker said he would place the patient under *x*-ray treatment, and hoped to bring him to a future meeting to show the results of treatment.

Tuberculosis of the Tongue.—Dr. Lapowski presented a man, 40 years of age, married for the past twenty years; he had four living and two dead children, but could not give the cause of the children's death. Twenty-one years ago he had a primary lesion on his penis, and was treated for syphilis for several months by means of internal administration of mercury. Since that time he had never seen any manifestation of any kind on his skin. He felt well until two years ago, when he began to cough. When seen for the first time, seven months ago, he had an ulceration on the left side of the back of his tongue of several months' standing, and leucoplakia on both mouth corners. The ulceration was in the shape of a curve with raised, infiltrated edges, the floor was covered with yellowish pus, and raised papillæ and pinhead-sized, punched-out ulcers were scattered over the floor. No glands were perceptible. In the apices of both lungs bronchovesicular breathing was very marked. Tubercle bacilli were found in the sputum. The patient looked pale and tired, but did not complain of any pain. He was given potassium iodide internally and was advised to go to the country for the summer. On his return he presented himself with the lesion on the tongue in the same condition as before. At the same time he complained of pain in swallowing. The speaker purposed treating him first with calomel injections, and then, when a marked improvement showed itself, to continue the treatment with rubbings.

Lichen Spinulosus.—Dr. Dana Hubbard reported this case. The patient, L. D., aged 25 years, was married, but had no children. She was pale and anemic. About two months ago she noticed a small patch of red spots appearing on her right arm, near elbow; this felt rough to the hand, was slightly itchy, seemed to catch in her sleeve, and at night seemed to have a tingling or burning sensation. As it did not disappear she applied at the Dermatological Class of the Vanderbilt Clinic. Dr. G. H. Fox diagnosed as above and gave a mixture of rhubarb and soda, 2 teaspoonfuls three times a day. Locally, soap poultices and hard scrubbing. The patient reappeared at the clinic in ten days with the patch smooth and less colored, but with other patches appearing—one on the forearm, one on the right thigh, and another on the left leg. The treatment continued. The lesion consisted of a pinhead-sized inflamed follicle with a hard, horny point or spine rising from it to a marked height. On passing the palm over the lesion it felt rough and file-like. Under the microscope the horny mass seemed to be nothing but epithelial cells packed close together. These lesions were numerous, very discrete, but in patches more or less irregular in outline and varying in size from one inch in diameter to three inches. On depilating the follicle there was left a distinct crater and adhering to the hair was the horny plug. The rash seemed to be easily controlled, but as soon as one spot was cleared others appeared, sometimes within twenty-four hours.

Late Results of the X-Ray Treatment of Cutaneous Epithelioma.—Dr. Charles Mallory Williams read this paper (see page 907).

Philadelphia County Medical Society.

At a stated meeting held November 14 Dr. Francis X. Dercum read a paper entitled "The Diagnosis and Treatment of Multiple Neuritis." Questions of etiology, symptomatology, diagnosis, and treatment were discussed at considerable length, and a woman of middle age who had largely recovered from an attack of multiple neuritis due to alcoholic intoxication and attended with mental symptoms was exhibited. Dr. Wm. Pickett presented a communication entitled "The Polyneuritic Psychosis (Korsakoff's Disease)." He pointed out that the disorder in question had been previously described by Dr. Mills, although its peculiar features were especially elaborated at a later date by Korsakoff. The disorder differs from other forms of multiple peripheral neuritis in the presence of a peculiar form of mental aberration characterized by fabrication or pseudoreminiscence. Dr. James Hendrie Lloyd read a paper entitled "Peroneal Palsy Following Childbirth." He showed by means of a skeleton that the lumbosacral cord and the branches of the sacral plexus may, under certain conditions, be compressed in the pelvis by the fetal head, particularly if the pelvis be deformed, and especially if forceps be used in delivery. Illustrative cases were reported. Dr. Wm. G. Spiller presented a communication entitled "The Diagnosis of Lesions, Especially Tumors, of the Conus and Cauda Equina." He dwelt upon the great

difficulty that at times attends the diagnosis of the lesions in question, simulating, as their symptoms often do, those of sciatica or peripheral neuritis or paresthetic meralgia or pelvic tumors. Dr. Arnold Lorand of Paris delivered by invitation an address on "Senility." He pointed out the similarity between the symptoms of senility and those of myxedema, and he expressed the view that senility is due to the withdrawal of the action of the thyroid secretion and that of other ductless glands. The factors responsible for the changes characteristic of old age consist especially in the various infections and intoxications, the effects of which in health are largely counteracted by the glandular organs of the body. All kinds of stimulants are harmful in this connection, as is also an excess of meat, and of salt in the diet. An interrelation exists between the various ductless glands. In counteracting the evolution of the phenomena of senility, it is important to stimulate the activity of bowels, kidneys, and skin. Medicinally iodides are of much service, and the therapeutic activity of thyroid extracts is referable to the iodine they contain.

Pathological Society of Philadelphia.

At a stated meeting held November 8 Dr. H. R. Alburger presented a specimen of "Aorta Showing Acute Infectious Thromboarteritis." Dr. C. Y. White exhibited a specimen of "Empyema from an Infant." The left lung was compressed by the accumulation of pus in the pleural cavity, while the heart was displaced to the left, the right lung being little, if at all, affected. Dr. White exhibited also specimens of tuberculosis of various organs from a colored child five years old. The mesenteric glands were enlarged and some bronchial glands were involved in marked degree. Other viscera exhibited the lesions of subacute miliary tuberculosis, and the brain was the seat of tuberculous meningitis. Dr. C. B. Farr read a paper entitled "Bronchial Calculi, with Report of a Case." The patient was a colored woman who had suffered from a cough for eighteen months. In certain positions of the body the breath-sounds were suppressed in portions of the lung, and skiagraphic examination disclosed the presence of shadows referable to enlarged bronchial glands. The calculus was expelled in a paroxysm of cough. The nature of the concretions, their mode of origin, the symptomatology of the condition, the diagnosis, and the treatment were all considered successively. Dr. J. D. Steele read a paper entitled "Some Observations Upon Sahli's Desmoid Test and the Musclenucleus Test." He contended against the view that there is a specific reaction between the digestive ferments and definite kinds of tissue, a principle on which depend many of the tests that have been proposed. For example, there is evidence to show that connective tissue in the form of catgut can be digested at times in the intestine as well as in the stomach, and also that the trypsin of the pancreatic juice is not essential to the digestion of meat-fiber and the destruction of the musclenuclei, while occasionally loss of musclenuclei may fail to take place in the presence of the pancreatic juices. A number of observations indicated that to be efficient large doses of such substances as pepsin and hydrochloric acid must be given in order to aid the digestion of connective tissue. Dr. R. S. Lavenson presented a communication entitled "A Probable Case of Typhoid Meningitis." The patient was a woman who gave a history of having had an attack of typhoid fever several years earlier, but who became ill while nursing a relative suffering from that disease. She presented symptoms of meningitis and lumbar puncture disclosed the presence of bacteria in the cerebrospinal fluid that on culture corresponded to typhoid bacilli. On post-mortem examination no lesion was found beyond a purulent meningitis, but owing to the conditions under which the autopsy was performed cultures from the meningeal exudate were not made, so that a demonstration of the bacteriological nature of the lesion was lacking.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Conferences on the Moral Philosophy of Medicine. Prepared by an American Physician. 12mo, 368 pages, flexible muslin. The Rebman Company, New York. Price, $1.50.

The Treatment of Syphilis. By Alfred Fournier. Second edition. Translated by C. F. Marshall, M.D., F.R.C.S. 8vo, 528 pages, muslin. The Rebman Company, New York. Price, $5.00.

The Diseases of Women, a Handbook for Students and Practitioners. By J. Bland-Sutton, F.R.C.S., and Arthur E. Giles, M.D., B.Sc. (Lond.), F.R.C.S. (Edin.). Fifth edition. 12mo, 536 pages, illustrated, muslin. The Rebman Company, New York. Price, $3.25.

Elementary Manual of Regional Topographical Dermatology. By R. Sabouraud; translated by C. F. Marshall. 4to, 660 pages, illustrated, muslin. The Rebman Company, New York. Price, $5.00.

The Health-care of the Baby. By Louis Fischer, M.D. 12mo, 144 pages, muslin. Funk & Wagnalls Company, New York. Price, 75 cents.

Aids to Gynecology (Students' Aids Series). By Alfred S. Grubb, M.D., M.R.C.S. (Eng.). Fourth edition, tenth thousand. 16mo, 136 pages, illustrated, muslin. William Wood and Company, New York. Price, $1.00.

Aids to Obstetrics (Students' Aids Series). By Samuel Nall, B.A., M.B., D.H.P., M.R.C.S., Eng. Sixth edition. 16mo, 145 pages, muslin. William Wood and Company, New York. Price, $1.00.

Applied Bacteriology. Revised and edited by Cresacre G. Moor, M.A., Cantab., F.I.C., with the cooperation of Richard Tanner Hewlett, M.D., F.R.C.P., D.P.H. Third edition. 8vo, 507 pages, illustrated, muslin. William Wood and Company, New York. Price, $3.50.

A Textbook of Histology. By Frederick R. Bailey, A.M., M.D. Second revised edition. 8vo, 497 pages, illustrated, muslin. William Wood and Company, New York. Price, $3.00.

The Medical Student's Manual of Chemistry. By R. A. Witthaus, A.M., M.D. Sixth edition. 8vo, 820 pages, illustrated, muslin. William Wood & Company, New York. Price, $4.00.

The Masters of Fate. By Sophia P. Shaler. 16mo, 358 pages, muslin. Duffield & Co., New York. Price, $1.50.

Rhythmotherapy. By Samuel S. Wallian, A.M., M.D. 12mo, 210 pages, illustrated, muslin. The Ouellette Press, Chicago. Price, $1.50.

On the Nature, Causes, Variety, and Treatment of Bodily Deformities. By E. J. Chance, F.R.C.S., Eng. Second edition. Vol. I. 12mo, 315 pages, illustrated, muslin. Smith, Elder & Co., London.

Diseases of the Digestive System. Edited by Frank Billings, M.D. 8vo, 824 pages, illustrated, muslin. D. Appleton & Co., New York. Price, $5.00, net.

Intoxications. By P. Carnot, E. Lancereaux, Letulle, Wurtz. 8vo, 352 pages, illustrated, paper. J. B. Ballière et Fils, Paris. 6 fr.

Die Röntgenstrahlen im Dienste der Neurologie. By Dr. Wilhelm Furnrohr. 4to, 375 pages, illustrated, paper. S. Karger, Berlin. Price, M. 10.

De l'Apepsie. By Dr. Henri Français. 8vo, 207 pages, illustrated, paper. G. Steinheil, Paris.

Carl Weigert und Seine Bedeutung für die medizinische Wissenschaft Unserer Zeit. Ein biographische Skizze von Dr. Robert Rieder. 4to, 141 pages, paper. Julius Springer, Berlin. Preis, M. 3.

Transactions of the Twenty-eighth Annual Meeting of the American Laryngological Association Held at Niagara Falls, 1906. 8vo, 347 pages, illustrated, muslin. Published by the Association in New York.

Toxicology, the Nature, Effects, and Detection of Poisons with the Diagnosis and Treatment of Poisoning. By Cassius M. Riley, M.D. Third revised edition. 12mo, 215 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.50.

Stohr's Histology, Arranged upon an Embryological Basis. By Dr. Frederic T. Lewis, from the twelfth German edition, by Dr. Philipp Stohr. Sixth American edition. 8vo, 434 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $3.00.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending December 1, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	319	162
Diphtheria	291	32
Measles	152	7
Scarlet Fever	136	8
Smallpox		—
Varicella	74	—
Typhoid Fever	87	20
Whooping Cough	55	5
Cerebrospinal Meningitis	10	4
Malarial Fever	.	. . . . .
Totals	1124	238

Currents of High Frequency in the Treatment of Ozena.—Tommaso Lucrezio finds in literature the records of eleven cases of ozena that have been treated up to date by the high frequency current. Two of these have been treated by him. The treatment is simple and easy of application when one has a proper apparatus, and the results are excellent. The current is applied by the monopolar method, the electrode being covered with paraffine, and thin enough to pass easily into the nasal passages. The cause of the good results is inherent in the nature of the morbid process, as well as the method of treatment. Ozena is an infective disease due to a specific microorganism of the group of Friedlander, called *Bacillus mucosus ozænæ*. A condition of hypertrophy and hyperplasia is produced, succeeded by one of atrophy. The mucosa becomes thinned and ulcerated, the glands of Bowman atrophy, as does the erectile tissue of the turbinated bones, until a naked bone surface is left to necrose and the nasal cavities are dilated. The process is essentially a diphtheritic one and may extend to the frontal and aural sinuses. A rational therapeutic plan will include removal of all crusts, efficient antisepsis, and excitation of the regenerative functions of the tissues. The rays do all three of these things. They do not act on the general sensibility. They may be used with high potential and an intensity of three ampères. Anesthesia of the nerves is produced, the combustion of the organism is increased, and there is an especial action on the vasomotor system and the blood plasma, as well as its cells. They have electrolytic and antiseptic powers by which they produce effects on ferments, microorganisms, and products of secretion. The muscular fibers contract, and with the aid of the electrostatic action the exudate is removed. Ozone is produced which acts as a disinfectant. At the point of contact of the electrode ischemia is produced, followed by intense and lasting hyperemia, and leucocytes undertake phagocytosis, so that the necrosed detritus is removed. The method gives better results than any other method of treatment, giving immediate relief and a rapid cure of this distressing condition.—*Annali di Elettricita Medica e Terapia Fisica.*

Experimental Atheroma of the Aorta Consecutive to the Action of Tobacco.—M. J. Baylac has experimented with tobacco in order to find out if it can produce atheromatous lesions in animals. He has made use of infusions and macerations. He made intravenous and subcutaneous injections. In all of these cases there were produced aortic lesions, which appeared sometimes in the form of small yellowish patches, making a prominence on the internal surface of the artery; sometimes in the form of hard plaques, calcareous and confluent at certain points; sometimes in the form of small aneurysmal dilatations. These lesions were in some cases limited to certain points, sometimes were desseminated throughout the length of the aorta. In a general manner the walls of the aorta were increased both in thickness and in consistence, and its lumen was enlarged. There was no appreciable lesion of the suprarenal capsules. Tobacco, like adrenalin, though less frequently than the latter drug, has an injurious effect on the arterial walls. This effect is especially marked if the tobacco is introduced by the intravenous method. These experiments confirm the observations of clinicians concerning the cardiovascular affections which are attributed to the abuse of tobacco.—*Le Bulletin Médica.*

Regeneration of the Internal Arterial Tunics After Curetting.—Ettore Vitale has experimented on animals by injuring the arteries in order to find out the method of repair of the walls. He finds that the portion of the internal coat that is injured is regenerated in all its constituent elements. The endothelium begins repair in sixty hours after the injury. After ten days the muscular and elastic tissues show signs of regeneration. The rapidity of regeneration is in relation to the severity of the injury. Simple detachment of the coat is soon repaired, muscular injury is repaired in from thirty-two to forty days, while complete disintegration is repaired in one hundred days. Elastic tissue is repaired more rapidly and more abundantly than muscular.—*Giornale Internazionale delle Scienze Mediche.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending November 30, 1906:

LEPROSY AS SEEN IN THE PHILIPPINES.

BY MAJOR CHARLES B. EWING,

SURGEON, U. S. ARMY, JOLO JOLO, P. I.

FORMER PRESIDENT U. S. ARMY BOARD FOR INVESTIGATION OF TROPICAL DISEASES IN THE PHILIPPINES.

WHILE leprosy, as seen in the Philippines, may not differ in many respects from the leprosy of other countries in races of dark skins, the distinctions are important and interesting. Aside from racial characteristics, the general features of this disease are the same, and, having been studied in the Philippines, the disease should be readily recognized in the most widely distributed peoples.

Leprosy is said to have been first introduced into the Philippines in 1633, when, it is related, the Emperor of Japan sent a ship containing 150 lepers to those islands to be cared for by the Catholic priests there. The seed was planted in this way, and as no means were taken to eradicate the disease the Franciscan fathers estimate that at the present time there are not less than 30,000 lepers in the archipelago, the major portion of these being in the Visayas. My own experience, however, would place the number far less than this. If the area of Luzon be placed at 40,000 square miles and this divided by eighty square miles (about the area in which twenty of my cases were found), and this quotient multiplied by twenty (as the average found in eighty square miles), the total would be 10,000 for Luzon alone. I am satisfied, however, that this average is much too high, and that the aggregate would be really much less than 10,000 for the entire Philippine Archipelago. A recent report verifies this view by placing the number of lepers at 3,683. My cases were found in the thickly-settled districts, whereas a very large portion of Luzon, Mindanao, and other islands I might mention are only sparsely settled or entirely uninhabitable, being an intermingling, in most part, of mountain, swamp, and virgin forest, impossible of cultivation.

Those lepers seen by me were Chinese and Filipinos, the latter consisting of Ilocanos and Tagalogs, but the Ilicanos formed four-fifths of the entire number of cases studied. All my cases were inhabitants of Northern Luzon, Manila, and Jolo; the Ilicanos residing in the Barrios of the provinces of Ilocos Sur and Union, the Chinamen in Trinidad, Province of Benguet, Luzon, and Jolo Jolo, P. I. The Tagalogs were citizens of Manila, P. I., isolated in the Lazeretto of that city. While this leprasorium contained, according to report, more than 100 cases, I only examined critically twelve tubercular lepers with a view to separating the bacillus lepræ from the discharges of the nose and the ulcerating lepromata of the face. The outline figure cards, here shown, were obtained in most part at Namapocan, Northern Luzon. As the military authorities were desirous of obtaining all the information possible on the subject of leprosy, I transmitted word to the Presidents of the various barrios in the neighborhood, asking that they send to me at Namapacan all lepers and persons suspected of having leprosy for examination. In this way I examined, through the aid of an interpreter, some fifty persons; finding out of that umber twenty-one lepers, from whom I made outline figure cards, using for this purpose the card issued by the Medical Department of the Army, in connection with the examination of recruits.

My studies are based upon thirty-six cases, and of this number I was able to obtain twenty-six outline figure cards. I procured in a few cases a complete history, as to the factor of heredity in leprosy; while in others data of this character were very meager and in a majority entirely unobtainable. It must not be understood that leprosy is so common in the Philippines that one meets it at every turn in the cities and villages of that country. I can testify that this is not so, for of all the cases observed by me a very small and insignificant number were unlooked for. I am therefore of the belief that the casual observer will fail to find much leprosy in his travels in the Orient, which is perhaps due in part to new sanitary regulations and laws requiring segregation, particularly in the larger cities. I do not recall seeing any leprosy in Zamboanga, Cotabato, Polyok, and Parang, situated in the Island of Mindanao; and at Jolo, in the Sulu Archipelago I saw only two cases in Chinamen, though the disease must certainly exist to a very considerable extent, as I am authentically informed, among Moros. I do not believe that leprosy affects the aboriginal inhabitants of Luzon to any great extent, as I saw only one case, and this in a Chinaman, among the Igorrotes of the mountainous districts of Abra and Benguet. From what I can understand, the Negritos are not much affected with this disease. These two tribes are said to be the original inhabitants of Luzon, and are essentially mountaineers, being seen only occasionally in the lowlands and seaport towns.

Of all the curious customs witnessed by me, associated with the different people of the Orient, those of the Igorrotes excited my curiosity the most. One especially which I may mention here as a "wake" or watch, which partakes of the nature of a ceremonial when a death occurs among them. Immediately upon the occurrence of a death the deceased is placed in a chair and a small fire or "smudge" is built under the chair, so as to correct the odors which may emanate from the body. The body is placed in the sitting position and the deceased's friends and relatives approach him, each making an obeisance begging that a tithing or present be given them. The dead are kept in the sitting posture for seven days with the smudge fire burning all the while. In the meantime the property of the deceased has been so distributed that a continuous banquet of solid and liquid refreshments has been served the relatives and friends, until the seventh

day arrives, upon which the dead is interred, a sufficient quantity of food and drink being placed in the grave for his use in the next world. If any misfortune should occur in the family of the diseased they may disinter the remains for the purpose of conciliating the angry spirits; this being accomplished, the body is again buried, and a renewed supply of food placed in the grave.

Relative Frequency.—Of the twenty-six cases of lepra studied by me, fourteen were males and twelve females. Of the fourteen males four had anesthetic, eight tubercular, and two mixed leprosy. Of the females three had anesthetic, five tubercular, and four mixed leprosy. Out of the total number of twenty-six cases of both male and female seven were anesthetic, thirteen tubercular, and six mixed leprosy. The proportion generally of anesthetic and tubercular cases amongst the males is slightly higher than amongst the females, though in the mixed lepra the female figures are 50 per cent. higher than the male. The proportion found by Impey in South Africa, out of 703 cases, was relatively the same as shown by me—of anesthetic cases 52.48 per cent., of tubercular 33.86 per cent., and of mixed lepra 11.53 per cent.

In cold climates the proportion of tubercular cases is always much higher according to Danielson and Boeck. These authorities found in Norway 51.6 per cent. of the cases to be tubercular, while only 33.3 per cent. were anesthetic, and 15.1 per cent. mixed. This preponderance of the tubercular type in cold countries is not merely a coincidence, but is shown to be due to the peculiar nature of the disease. On the other hand, the prevailing type of lepra in all warm and temperate climates is said to be the anesthetic variety.

Form.—Leprosy occurs in the Philippines in four forms—the anesthetic, the tubercular, the mixed, and the syphilitic. Generally and briefly, it may be stated that in the anesthetic form of this affection the nerves of the extremities and face are diseased, producing atrophy and ulceration of the tissues, paralysis, and contraction, leading finally to partial and complete amputation of digits; in the tubercular type of leprosy the skin of the face, the hands, and the feet become the site for the tubercles or lepromata; in the mixed form the tubercular and anesthetic forms are combined in the same patient, and in syphilitic lepra the leprotic manifestations are modified by the presence in the system of the syphilitic poison.

Cause.—The universally acknowledged cause of leprosy is the *Bacillus lepræ*. If the bacillus attacks the nerves we have anesthetic lepra; if it attacks the skin, tubercular leprosy; if it attacks both nerves and skin, mixed leprosy results, and if the bacillus attacks the patient suffering from syphilis, or if syphilis is contracted by a patient suffering from leprosy, we have syphilitic leprosy. The bacillus possesses a striking resemblance to the bacillus of tuberculosis, both morphologically and as regards staining reactions. Hansen discovered the organism in 1874, and his observations were confirmed by Neisser, working independently in 1879. Its average length is five to six microns; a little longer and somewhat thinner than the tubercle bacillus, although variations in size may occur. The frequent beaded appearance has led some observers to believe that spores were found; this, however, is doubtful. I was able to find the organism in the discharges of ulcerating lepromata located on the face in the tubercular lepers examined by me at the Lazaretto, Manila. I was not successful in finding the bacillus in the dust of the floor or walls of the large and commodious approach to the Lazaretto, which formed the lounging place for the 100 or more lepers confined in this leprasorium. I was able to find the lepra germ in the discharges from the nose in several cases of tubercular leprosy, which location is said by the India-German Leprosy Commission report (truthfully, I think,) to be the primary seat and place where the bacilli are almost invariably found. Stricker verifies this, having found the *Bacillus lepræ* in the nasal mucus in 128 out of 153 lepers examined, and considers the initial lesion of the disease to be a specific ulceration of the cartilaginous septum of the nose which persists and is an active source of infection during life. Related to this condition, he maintains that epistaxis is often an early symptom. Repeated examinations of leprous blood gave me only negative results. In severe cases the anemia was well marked, especially in the old. The hemoglobin is said by some observers to be not relatively high. I was not disappointed, however, in finding no growth from the blood and discharges from the nose and ulcerating lepromata, because this was not expected, as no one has been able to grow the organism on artificial media. Campana of Rome claims to have been successful in growing stale cultures on glucose agar, but this observation has not been verified.

Histologically, leprosy belongs to that group of granulomata which includes syphilis, lupus, tuberculosis, and diseases of this character. The neoplasm is made up largely of connective tissue of a partially reverted type. In this new growth, especially when it forms the tubercular variety of leprosy affecting the skin, the organism is found in extraordinarily large numbers; but in the anesthetic form, however, when the peripheral nerves are first attacked, they are greatly increased, though one observer, Impey, has failed to find them here. Besides the two common locations, the skin and the nerves, the bacillus may be found in the mucous membranes, cartilages, spleen, liver, lymphatic glands, hair follicles, cornea, testicle, spermatic cords, ovaries, walls of blood-vessels, kidneys, and mammary glands. They are not found in the muscles, bones, spinal cord or joints; nor in the bullæ and other secondary lesions, nor in the urine or menstrual discharges. The physiological secretions do not contain them.

Hansen, one of the great leprologists, states that the brain is never affected by leprosy. This has been disproved, however, as the *St. Petersburger medizinische Wochenschrift,* October 17, 1890, contains a report by Dr. C. Brutzer, of ten lepers who had died in the leprosery at Riga, four of these having had adhesions between the dura mater and the brain, and in three of four cases of adherent meningitis he found lepra bacilli around the pituitary gland.

Communicability and the Modes of Infection.—Contagion: Leprosy is now generally believed to be contagious, and the factor of heredity has little, if anything, to do with its spread. Out of twenty-one of my cases where information was obtainable, only one (or 4.7 per cent.) gave a history of leprosy among the parents; in the case of one tubercular leper the father had died of leprosy. Impey states that 266 leprous parents confined in the Robben Island Asylum, Cape Colony, had 951 children, and only twenty-three of these, or less than 3 per cent. of the children, became lepers. He also states that of 520 lepers in the asylum mentioned 475 were born of healthy parents. Of the remaining forty-five cases the father alone was infected in

twenty-five, the mother alone in sixteen, and both father and mother in only four cases. Of the numerous offspring of 160 children of leprous parents that have migrated from Norway to the United States, Hansen says not one has become leprous. Leprologists of wide experience have failed thus far to see a newborn leper, and the youngest cases are rarely under three or four years of age.

In proof of the contagion theory it is known that the bacilli given off from open sores are found in the saliva and nasal secretions. Schaffer was able to collect lepra bacilli on clean slides, placed in close proximity to lepers whom he caused to read aloud.

Inoculation: Experimental evidence is inconclusive in this respect. The Hawaiian convict under sentence of death, inoculated by Arning September 30, 1884, had rheumatoid pains and neuritis of the ulnar and median nerves, but while the neuritis subsided, a small leproma developed at the site of inoculation. Three years after the inoculation the disease was well marked and the man died of leprosy in 1890, six (6) years after inoculation. This case, however, is thought to be inconclusive, as the convict has leprous parents and lived in a country inhabited by lepers. Successful inoculations of the lower animals have not been made, though Melcher and Orthmann inoculated the anterior chamber of the eye of rabbits with leprous material and claimed that the extensive growth of nodules in the internal organs and lungs contained lepra bacilli. This observation has remained unverified.

Conditions that Influence Infection.—Baelz believes that leprosy is very feebly contagious, if at all. He has treated lepers for years in the same wards with his other patients, and during that time none of his nurses or any of his sick who came in contact with them ever contracted the disease, though no special precautions were used. Data of five thousand cases collected by him from Japanese physicians show that in only two instances could it be proven that the disease had been conveyed directly from one person to another. It must be understood that infection implies a morbid process by which pathogenic microorganisms are introduced into the body, and subsequent reproduction there. Infectious diseases may be directly or indirectly communicated from one person to another. Directly infectious diseases are termed contagious, and the infecting agent is known as contagion. Welsh says that "whether or not an infectious disease is contagious in the ordinary sense depends upon the nature of the infectious agents, and especially upon the manner of its elimination from and reception by the body. Most, but not all, contagious diseases are infectious; scabies is a contagious disease, but it is not infectious."

The closest and most intimate contact is necessary, though the disease attacks persons of all ages. Father Boglioli, in New Orleans, and Father Damien, in the Sandwich Islands, fell victims to this disease while in the discharge of their duties as priests. The theory held by Jonathan Hutchinson that the susceptibility to this disease is increased by fish diet, or that the poison is introduced through the medium of fish, remains to be proven. Besnier explains the long incubation period on the ground that, by reason of bad soil, the bacilli lie dormant and are unable to multiply. Thin, while believing that close personal contact is usually necessary, thinks the mosquito or acarus may, possibly, be an intermediary in transmission. Morrow believes that the contagion finds entrance to the body through the mucous membranes of the respiratory and gastrointestinal tracts, the bacillary origin of leprosy being admitted. I am satisfied that in my cases the predisposing causes were bad hygiene, dirt, filth, and careless habits. As is well known, the Filipinos of the lower classes are not cleanly. Filipinos as a rule congregate in villages, though in some instances one may find detached dwellings. This concentration of people is not attended with increased sanitary effort, but, on the contrary, a supine indifference is manifested. While, as a rule, the habitations are raised on piles and the living rooms placed some ten or twelve feet above the ground, in the larger towns and cities, commercial conditions require that business be transacted on the ground floor; hence many of the lower orders eat and sleep in the rooms which hold their wares. The poorer classes are essentially dirty; hence these become afflicted with leprosy, this disease being very rare among the higher classes. The surroundings of Filipino dwellings generally are filthy, and only in the cities does one find anything approaching a privy vault. For the most part, feces are permitted to fall upon the ground immediately under the habitation and instead of a sanitary squad and disinfectants alleviating the nuisance, the lowly pig takes upon himself these functions, by consuming the excrement; hence pork as an article of food is held at a discount by the intelligent American, though the Filipinos still regard it as a delicacy. Again culinary utensils are limited; these for the most part take the various forms of earthen ware which are much in general use. The fingers not infrequently take the place of forks, and the incisor teeth become a substitute for the knife. A single drinking cup may be used by an entire family. While the bedstead is in general use by the middle and higher classes, the lower, from necessity perhaps, takes more kindly to the floor, and it is not unusual to find a whole family sleeping in a single room. The clothing worn by day is used as a sleeping garment by night. Besides the unhygienic conditions noted, the hot, moist climate is doubtless a potent but still an indeterminate factor in the propagation of this disease among Filipinos.

Period of Incubation.—It was impossible to get exact data as to the length of this period in all the cases seen by me. From the statements made by friends and relatives, four months seemed to be the shortest and five years the longest period of incubation. Impey gives the average duration of this period as two years, and authorities are agreed that it may vary from a few weeks to many years. Danielssen, Leloir, and Hoegh report cases in which the periods of incubation lasted ten, fourteen, and twenty-seven years, respectively.

Prodromes.—The prodromal stage follows that of incubation and precedes the eruptive or macular stage. This consists principally of chills, fever, sweats, and unaccountable feeling of weakness, accompanied by drowsiness and a tendency to fall asleep at unusual times. This last was especially marked in several of my cases, and particularly well pronounced in an anesthetic leper named Santiago, a Chinaman, who would fall asleep while in conversation and sleep for hours at a time. Other symptoms were dryness of the nostrils, headache, perversions of sensation; such as hyperesthesia, "pins and needles" in the extremities, also intermittent neuralgic pains in the limbs and face, as well as rheumatic pains in the back, loins, and elsewhere, these lasting months, preceding and leading up to the explosion of leprosy. In all my cases

except four, and in two of these, history was unobtainable; the fever and sweats characterized the prodromal stage of leprosy in all its different forms. Of the anesthetic type there were prodromes in five cases out of seven, no history being obtainable in the remaining two; of the tubercular form prodromes in seven cases out of nine; of the mixed variety, prodromes was present in all six cases. Both the remittent and intermittent forms of fever, of greater or less intensity, were seen in this disease, which may readily be mistaken for malaria in tropical countries. Febrile attacks from a week to a month's duration, alternating with profuse sweats, may occur off and on during one or two years. The curious feature of these sweats is that they generally affect the body or trunk, while the limbs are frequently not involved in the hyperhidrosis. I noted anidrosis in seven cases, and these nonsweating spots became anesthetic later in the disease. The sweats and fever were noted in every case where any history was at all obtainable, and with the lancinating and "pins and needles" pains, formed the most common symptoms of the prodromal stage, which racked the unfortunate sufferer from one to two years. I must also mention particularly the early involvement of the mucous membrane of the nostrils, characterized by a peculiar dryness, which later became almost invariably the seat of ulceration. Care must be exercised, however, in diagnosis; that this should be not confounded with the manifestations of nasal syphilis. The symptoms of peripheral neuritis are as a rule earlier and more pronounced in the anesthetic than in the tubercular variety of leprosy, though neuralgic pains may accompany the formation of lepromata in the tubercular form at a later period. In only two of the twenty cases in which a history was obtainable were constitutional symptoms lacking prior to the appearance of the macular eruptions, this being quite in accord with the findings of others, where a complete absence of constitutional symptoms is noted only in a very small proportion of cases before the eruption.

The Primary Eruptive or Macular Stage.—In most of my cases the common prodromal phenomena preceding the eruption were an unusually severe outburst of fever, or a period of indifferent health. The eruption is distinctively macular as the areas of discoloration are not elevated above the general level of the skin, but may vary in different cases as to size, number, and duration. The spots range from the size of a dime to those that may occupy many inches of surface; they may be few or many in number. The duration extends from a few days to months and even years, as Danielssen quotes a case where the spots remained unchanged for eighteen or twenty years. The color of the maculæ likewise varies, for while the earlier spots in some cases are purely erythematous, darkest in the center, shading off toward the periphery and disappearing on pressure, in other cases the spots seem to be pigmented from the outset or merely vitiliginous patches. I noted quite a number of cases in which all three forms of the erythematous, pigmented, and vitiliginous maculæ occurred in the same individual. The ring form of macula was quite noticeable, where the center of an erythematous patch cleared up, the periphery remaining red, or took on pigment, so that the affected spot presented the appearance of a dark or red ring, sometimes incomplete, however, inclosing a patch of pale anesthetic skin. These rings were sometimes found to be hyperesthetic while the enclosed areas were usually anesthetic. Briefly, then, the primary macular eruption is most frequently seen on the face, the nose, cheeks, ears, and especially the superciliary region, the extensor surfaces of the limbs, the dorsal surfaces of the hands, the buttocks, back, abdomen, and chest. The scalp is never, and the soles of the feet and palms of the hands rarely, if ever, attacked. The absence of leprous eruption in the scalp and leprous alopecia was so general in my cases that it forms to me one of the most striking diagnostic differences between leprosy and syphilis. Another striking circumstance noted by me was that those parts of the face most prone to leprous eruptions, particularly the superciliary region, suffered an early partial or complete loss of the eyebrows. Of twenty-two cases the eyebrows were completely lost in eleven, partially lost in eight, and not noted in three.

In my cases of the anesthetic type the eruption seemed to be more marked and more widely distributed than in the tubercular variety of the disease, and were distinctly symmetrical in many; while in the tubercular form the eruption was not so well marked, of shorter duration, more localized, and frequently asymmetrical.

Stage of Specific Deposit.—Sight and touch failed to disclose during the macular stage any very well-marked changes in the skin as the result of thickening or new growth, but this is followed by a period of tissue development or deposit, showing most strikingly the impress of specific characters. This tissue change or deposit may affect either the skin, peripheral nerves, or both. If in the skin, tubercular or nodular leprosy results; if in the peripheral nerves, anesthetic or nerve lepra ensues; if in both localities, then mixed leprosy is the consequence. Where syphilis has been acquired by a leper, or leprosy has been grafted upon a syphilitic, the clinical features of leprosy are greatly modified. While all three forms of leprosy proper when fully developed have much in common pathologically; clinically, they are fairly distinguishable. A very brief description of them as seen in my cases will suffice.

Anesthetic or Nerve Leprosy.—Here the prodromal and macular stages may be severe, slight, or entirely absent; usually, however, there is a well-marked macular stage of long duration, which is quite exceptionable in tubercular leprosy.

In my anesthetic cases the ring form of eruption is quite common, the red congested, somewhat elevated frequently hyperesthetic border, enclosing a pale area of integument of variable size, anesthetic and nonsweating. The ring form, resembling somewhat the body ringworm so common to natives of tropical climates, may be preceded or associated with large areas of erythematous pigmented or vitiliginous patches covering the extensor surfaces of the limbs, hands, feet, and face. This eruption is generally bilateral and may give place later to a specific infiltration of the skin, which is likewise symmetrical and usually anesthetic, though earlier the needle may show it to be hyperesthetic.

I invite the reader's attention to the outline figure cards of an anesthetic case of leprosy (Fig. 1) which show ulcers, cicatrices, and leucospots of various sizes distributed on the hands, feet, knees, and back of the thighs, caused primarily by ruptured bullæ. These bullæ form suddenly and rupture, exposing reddish surfaces which crust over, turn pale, become anesthetic, and have pigmented borders. If the bullæ form close together they usually ulcerate, producing large, superficial, serpiginous-looking sores, which after a variable period finally heal and become anesthetic. This appearance of bullæ, *pemphigus leprosus*, is

very characteristic and distinctive of this form of leprosy. The bullæ while characteristic of the early skin lesions may also occur later at any stage of the disease.

The most prominent symptoms of nerve leprosy in my cases were skin lesions, but the nervous system becomes profoundly involved as evidenced by increase of neuralgic pains, formication, hyperesthesia, and anesthesia. The lymphatic system likewise becomes affected and the glands of the groin, axilla, neck, and throat are particularly implicated. While in the majority of my cases the lymphatic glands generally were enlarged bilaterally, nine of the twenty-two (three anesthetic, three tubercular, and three mixed), as shown in the outline figure card, gave evidence of marked adenopathy, where the enlargements reached the size of walnuts, particularly in the inguinal region, though the axillary and cervical glands were affected to a less extent. In a number of cases the interference with breathing and swallowing from this cause was marked, and in several instances I noticed fistulous tracts leading from the glands, discharging softened and broken-down material. Pus organisms are thought to be the cause of the glandular enlargement, though lepra bacilli are found in the glands. The nervous system seems to have become chiefly involved at this stage of the trouble, for the peripheral nerves give distinct evidence of disease; the neuralgic pains are increased as a result of nerve destruction, and the dominant elements are well marked hyperesthesia, anesthesia, and paresthesia, associated with trophic changes in skin, muscle, and bone. My attention was particularly directed to thickening and enlargement of the ulnar nerve at the elbow, median at the wrist, and peroneal at the knee, while changes in the tibial, radial, and brachial were noted in a less degree. Some smaller nerves, superficially located, were found by palpation to be hard and cord-like. These thickened nerves in some instances were tender on pressure and the parts supplied by them were hyperesthetic and acutely neuralgic. In the majority of my cases, however, I have found that the hyperesthesia and neuralgia had given place to anesthesia, paresis, muscular atrophy, and other trophic changes, resulting from progressive nerve disturbance. In no instance did the anesthesia come on without the neuralgic pains, hyperesthesia, discoloration of the skin, and constitutional symptoms, though this is said by leprologists to be not uncommon. My notes show that in two cases only were there no prodromes prior to eruption. The anesthesia in nerve leprosy begins commonly in the feet, thighs, hands, arms, forearms, and face, and more rarely the trunk may be involved.

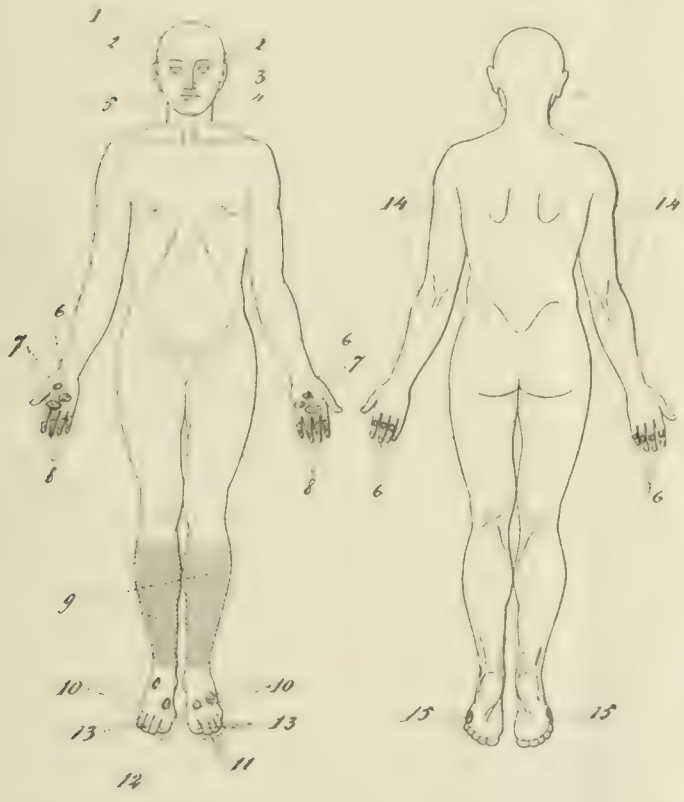

Fig. 1.—Anesthetic (atrophic) leprosy: 1, No loss of hair; 2, no eyebrows or eyelashes; 3, no bridge of nose; 4, blue lines around the gums; 5, gums retracted; 6, 6, leucopatches, sensitive; 7, 7, thenar and hypothenar eminences melted away; 8, 8, flexors contracted, phalanges shortened, distorted, and bent upon palm; 9, surface brawny, indurated, and anesthetic; 10, 10, suppurating sores, 3 in. long; 11, toes lost; 12, great toe much swollen; 13, 13, feet much swollen and disfigured, extensors contracted, and phalanges turned upward; 14, 14, extensor muscles of arms atrophied; 15, 15, leucopatches, sensitive.

The permanent seats of eruption invariably become thickened and anesthetic, this being determined by the use of a sterilized needle. These anesthetic areas were markedly symmetrical and of large extent in nerve leprosy, while less commonly symmetrical, of smaller area, and more localized in nodular leprosy, though in the mixed form these features were governed by the primary type of the disease. Muscular deformity is essentially a characteristic feature of nerve leprosy. The atrophy of the muscles of the extremity and face keep progress with the increased anesthesia, and the result is particularly marked in the extremities, where it is associated with distortion of the hands and feet, and loss of motion. In the face, paralysis and atrophy of muscles, due to involvement of the facial and motor occuli nerves, were seen in a few cases. Deformity of the extremities existed in six out of seven nerve, and three out of six mixed lepers, indicating in the latter nerve leprosy as the dominant type of the associated forms.

Three of the nine tubercular cases showed swollen hands and feet, bulbous fingers and toes, indicating nerve involvement and commencing change to the mixed form of the disease.

The facies in nerve leprosy is almost as characteristic as that of leontiasis in the nodular type, for the paralyzed face, drooping and everted lids, cornified conjunctivæ, paralyzed lips, retracted gums, and dribbling mouth, produce a picture which once seen is never forgotten. Such was the image portrayed in the Chinese leper, Santiago, number fifteen of my series. The deformities in the hands and feet, as seen in nine of my cases, were even more characteristic than those of the face, for there was marked feebleness in the arms, the forearms were wasted, the grasp weakened, the thenar, hypothenar eminences, and interossei melted away, and the *main-en-griffe* or "lepra claw" was produced; like changes occurred in the legs and feet, so that walking was greatly impaired, especially in two cases of nerve leprosy (lepra mutilans) where the toes were amputated by a process of what seemed to be dry gangrene; in a few cases the distortion of fingers and toes seemed due to what I believe to be interstitial absorption, where the shaft of the phalanges wasted more rapidly than the articular surfaces, without destruction, but merely a shrinking of the fleshy

part. A very striking feature is presented here, where the distorted, stump-like finger may be crowned with a talon-like nail, or the nail may be seen to spring directly from the knuckle as seen in Nos. 3, 4, 5, and 6 of my series of anesthetic cases. The course of anesthetic leprosy is much slower than that of the tubercular form and varies in length from ten to thirty, though cases are recorded where the duration extended to forty years. The average duration is thought by many to be eighteen years. The nerve cases up to the time of my seeing them had existed from one to fifteen years. Death usually takes place through marasmus, amyloid degeneration of the kidneys, or exhaustion resulting from enteric complications.

Tubercular or Nodular Leprosy.—This form existed in thirteen of the twenty-six cases studied by me, and it was learned that the preliminary prodromic period, of variable length, usually ushered in a tolerably well-marked macular stage (short, however, in comparison with nerve leprosy) with a smart attack of fever. The essential and most characteristic element in tubercular leprosy is the leproma. (See Fig. 2.) In my cases lepromata were invariably seen on the superciliary and malar regions of the face, chin, nose, lobes of ears, and less frequently upon the extensor surfaces of the arms, wrists, backs of the hands, thighs, and groins. The lobe of the ear seemed in my cases to be an early and favorite site for lepromata, as my outline figure cards show it in every one of the thirteen tubercular lepers studied. This observation is in accord with that made by Unna upon tubercular leprosy. The normal fate of the leproma is to soften in the center and to be absorbed, the usual result being a circular patch of smooth scar tissue, or after softening it may ulcerate and discharge a sticky, yellowish pus. When the discharge dries up the ulcer may heal underneath, leaving an irregular depressed scar. I was able to demonstrate the *Bacillus lepræ* in the ulcerating lepromata of the face in all of the tubercular lepers seen by me at the Lazaretto of Manila. The favorite seat of ulceration semed to be in those lepromata situated upon the malar and adjacent regions of the face, though I know of no particular reason for this, as those located upon the extremities are more prone to ulceration. My method was to use sterilized platinum wire in obtaining secretion from lepromata, and after placing this on a cover glass I followed this routine: (1) Fix by heat (passing through flame); (2) stain with carbolfuchsin solution (Zeihl's) for a few minutes; (3) wash in water; (4) decolorize with 5 per cent. sulphuric acid; (5) wash in water; (6) counterstain with aqueous solution of methylene blue; (7) mount and examine with microscope.

This affection is so terrible and the appearance presented by Filipino lepers is so frightful that, while in the writer's experience it has no counterpart, he can only compare the picture in these respects to cases of variola pustulosa hæmorrhagica as seen in the negro at Namapacan, Luzon.

It is well to note that in my tubercular cases the few cutaneous manifestations consisted of an eruption of erythematous spots or blotches which appeared and disappeared a number of times before the characteristic tuberculation developed. The macules were usually oval or circular in shape, of a reddish brown or coppery color, sometimes fading into a dirty yellow. In some instances the macules presented a purplish or vinous hue resembling Port wine discolorations; were slightly elevated and distinctly demarcated from the sound integument. Usually the skin of the face was thickened and swollen, presenting an appearance of edema. The extensive diffuse infiltration due in my instances to a coalescence of circumscribed patches, may remain permanent and instead of undergoing resolution become elevated into nodular excrescences, or the tubercles without going through a preceding phase of infiltration, may develop upon new surface. The tubercles vary in size from a pea to a walnut, and by aggregation may form elevated masses of considerable extent. While the forehead, nose, lips, chin, cheeks, and ears, the hands and extensor surfaces of forearms, are the sites usually affected, any portion of the body surface may be the seat of tubercular deposit except the scalp. The course of the tubercles and infiltration varies. They remain stationary with but little variation for months and years, the change being in the nature of slightly desquamating surface, or the color changing into a yellow or dark brown. Gradual involution may occur, having pigmented stains or scars. There

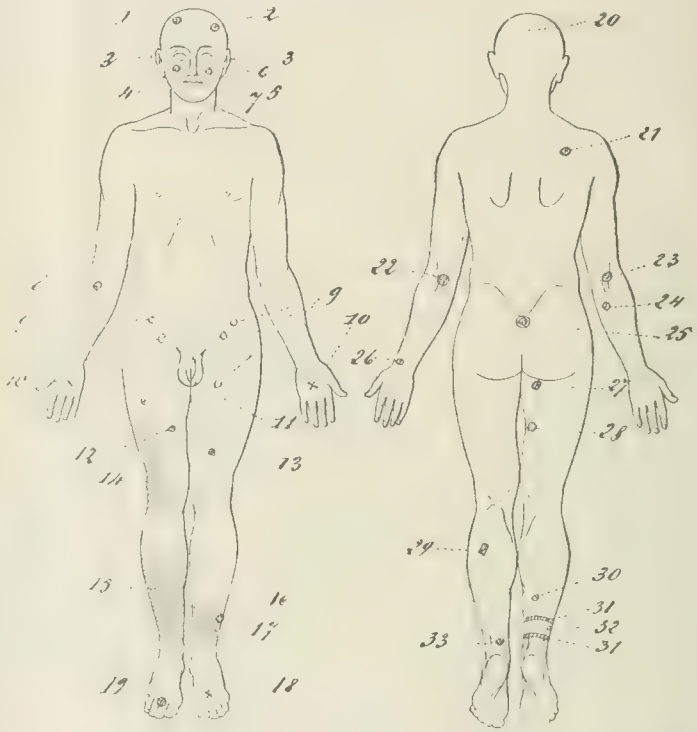

Fig. 2.—Tubercular (hypertrophic) leprosy: 1. Sweat spot, 1½ x 1 in.; 2, sweat spot 1 x ⅝ in.; 3, 3, ears enlarged 3⅜ x 1⅛ in.; there were two hairs on the left eyebrow, eyelashes completely lost; 4, elevated tubercle ⅝ x ⅜ in., with ulcerated spots in center; 5, tubercle ⅞ x ⅝ in., with red spot in center with whitish tip (new tissue felt); 6, bridge of nose sunken, vomer lost; 7, upper lip much swollen; 8, incipient elevation, 1-16 in., with smooth center; 9, 9, enlarged lymphatic glands, each the size of a walnut; 10, 10, palms and fingers of hand purple, as if from blood stasis; 11, numerous small elevations on scrotum, no hair except near thigh on either side; 12, tubercle 3-16 in. diameter; 13, dark ring ¾ x ⅝ in., with white center; 14, insensitive area, 7⅛ x 4 in.; 15, insensitive area 7½ in. long over the entire front of leg, skin splitting, elevations slight at present; 16, dark ring, ⅝ in. diameter, with white-tipped center, insensitive; 17, insensitive area 6½ in. long covering entire front of leg; 18, feet somewhat swollen, evidently from disease; 19, dark spot, 1¼ x ¾ in., with white center; 20, slight loss of hair; 21, black spot 1-3 in. diameter; 22, oval scar ¼ x 1 in., recent skin gone not ulcerated; 23, circular elevation 1⅛ in. diameter, insensitive; 24, dark ring 3⅛ x ⅜ in., with white line running through entire length, insensitive; 25, sweat spot 3 x 2 in.; 26, insensitive area 3⅛ in. diameter, with scab on center; 27, circular elevation 1 in. diameter, black, with white center; 28, black ring 1½ x 1 in., encircling white-tipped elevation; 29, smooth dark patch 1 x ⅞ in., white toward the center; 30, circular spot 9-16 in. diameter, dark blue with whitish center; 31, 31, elevated bands ¼ in. wide, dark blue in color; 32, circular elevation ⅝ in. diameter, reddish scab on top; 33, black circle 1½ x ⅝ in., with three white spots within.

may be a development of successive crops from the same region at more or less prolonged intervals. The tubercles, however, instead of disappearing by a process of resolution, may soften, break down, and disintegrate, forming shallow, indolent ulcers with a yellowish, somewhat offensive discharge.

The face was the seat of the most marked and characteristic development of tubercles, and in the advanced stages of some of my cases the infiltration took the form of prominent bosses or ridges divided by deep furrows; the lepromata ran together and caused much disfigurement due to the bulging out of the frontal and supraorbital skin upon

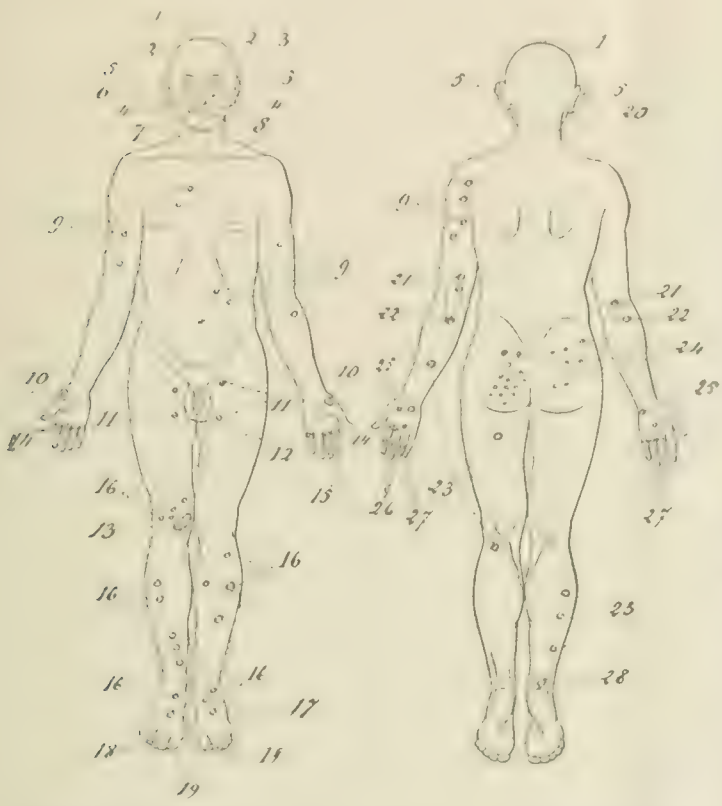

Fig. 3.—Mixed leprosy: 1, No loss of hair; 2, 2, eyebrows absent; 3, primary focus of disease; 4, 4, small nodules on face ¼ in. diameter; 5, 5, ears nodular and enlarged; 6, vomer melting away, process began four years ago; 7, mouth breathing, gums receding; 8, hair of moustache and beard lost; 9, 9, small raised nodules ¼ in. diameter, insensitive; 10, 10, flat nodules 2 in. diameter; 11, 11, lymphatic glands enlarged; 12, scrotum enlarged; 13, scar 2½ in. diameter, insensitive; 14, 14, ulcers ½ in. diameter; 15, second and third fingers of left hand flexed to a right angle, those of right hand partially flexed; 16, 16, 16, 16, tubercles ½ to 1 in. diameter; 17, legs enlarged, toes bulbous, feet swollen, and splay; 18, 18, toenails absent; 19, great toenails broken and shredded; 20, tissues of neck infiltrated on both sides; 21, 21, healed ulcers and leucospots of irregular contour about 1 in. diameter; 22, 22, ulcer over each olecranon 1 in. diameter; 23, 23, insensitive nodules ¼ in. diameter; 24, small, insensitive nodules ⅛ in. diameter; 25, 25, flat, insensitive nodules 1 in. diameter; 26, nodules 1 in. diameter; 27, 27, nails broken and shredded; 28, leucospot of irregular contour 1½ in. diameter.

which was situated superimposed nodular masses thrown into immense folds overhanging the eyes; the skin of malar cheek regions formed large cushion-like tumefied masses. The alæ of the nose broadened out associated with a flattening and sinking in of that organ; the lips were thickened and protruding, the chin swollen and heavy; the external ear greatly enlarged so that the lobes hung down (particularly in one case) in flabby, pendulous masses almost to the shoulders.

This repulsive, dusky, bloated, wrinkled, greasy countenance is very appropriately designated leontiasis.

Another strikingly characteristic feature of tubercular leprosy is the plaque, which is formed by the confluence of individual tubercles. The plaques are usually large in size, dark in color, may desquamate slightly, and are situated most commonly on the extensor surfaces of the limbs where they are said to last for years unchanged, always indicating the utmost chronicity of this type of the disease. The hair covering both tubercles and plaques usually becomes white, downy, or splintered, before falling out. The duration of nine of my cases of tubercular leprosy, where history was obtainable, ranged from one to eighteen years—the average duration being five and two-thirds years up to the time of my seeing them. Morrow places the average duration of this type of leprosy at eight years, Manson at eight to nine years. Death may ensue from pulmonary, renal, or intestinal complications, marasmus, and leprous exhaustion.

The writer has completely failed to observe among Filipinos that remarkable phase of leprosy described by Danielssen and Boeck as an acute form of this disease similar to acute tuberculosis. The manifestations as described by them are a continuous fever of some twelve days' duration, when raised, shiny, bluish spots appear over almost the entire body. The spots increase rapidly in size and firmness, become confluent and progress with such rapidity that in a few weeks they attain a growth which, in the ordinary form, it has required years to reach. The constitutional symptoms abate upon the appearance of the eruption, tubercles soften, and the affection becomes chronic. When the cutaneous eruption fails to appear, the patient usually dies in the course of a few days from pneumonia, pleurisy, or meningitis.

Mixed Leprosy.—Here the lesions do not differ in any way from those mentioned, hence this form of leprosy calls for no detailed description. (See Fig. 3.) This term is meant to imply an association of the anesthetic and tubercular types in the same person. While leprologists of the highest repute are agreed that most tuberculous lepers finally become anesthetic, the contrary is thought to be true to a far less extent, and a combination of both anesthetic and tubercular lesions may coexist in some from the beginning. The marked tendency of some of my old tubercular cases to pass gradually into the anesthetic form is quite in accord with the holding of Hansen and Looft, who think that this is the natural termination of all cases of tubercular leprosy; Impey believes, on the contrary, that every case of mixed leprosy is such from the very outset of the disease.

The physical condition which is the final outcome of the unfortunate victim of tubercular leprosy is so graphically portrayed by Leloir that I quote it here: "If the patient does not die of some intermittent disease or special complication, the unhappy leper becomes a terrible object to look upon. His deformed leonine face is covered with tubercles, ulcers, cicatrices, and crusts. His sunken, disfigured nose is reduced to a stump. His respiration is wheezing and difficult. A sanious, stinking fluid, which thickens into crusts, pours forth from his nostrils. The nasal mucous membrane is completely covered with ulcerations. A part of the cartilaginous and bony framework is carious. The mouth, throat, and larynx are mutilated, deformed, and covered with ulcerated tubercles. The patient breathes with the greatest difficulty and is threat-

ened with frequent fits of suffocation, which interrupt his sleep. His eyes are destroyed, and not only his sight, but his sense of smell and taste are completely gone. Of the five senses, hearing alone is usually preserved. Owing to the thickened and pachydermic state of the skin of the limbs, which gives to them the appearance of elephantiasis, and to the presence of ulcerating tubercles, crusts, and cicatrices, the sense of touch is abolished. Usually at this time the peripheral nerves are involved, so that the symptoms of both the tuberous and the anesthetic type of leprosy are present. The patient suffers excruciating pains in the limbs, and even in the face, while the ravages of the disease in his legs render walking difficult and even impossible. From fistulous openings in the hypertrophied inguinal and cervical glands pus flows abundantly. In certain cases the abdomen is increased in size on account of the involvement of the liver, spleen, and mesenteric glands. With these visceral lesions the appetite is irregular or lost. There are pains in the stomach, diarrhea, bronchial and pulmonary lesions, intermittent febrile attacks, and a hectic state. The peculiar smell, recalling that of the dissecting room, mixed with the odor of goose feathers or of a fresh corpse, was recognized but badly described by authors of the middle ages, who compared it to that of a male goat. This is the complexus of symptoms which the patient presents unless some fatal complication has come to his relief. In this light one can understand how, in the ancient poem of Job, leprosy is called 'the eldest daughter of death.'"

Pathology.—All the lesions of leprosy are now thought to be due, directly or indirectly, to the multiplication of the *Bacillus leprœ* in the tissues. As stated before, in length the bacillus is one-half to two-thirds, and in breadth one-sixteenth the diameter of a red blood corpuscle. The bacillus reacts to certain staining reagents (carbol-fuchsin, after treatment with mineral acids) similar to the *Bacillus tuberculosis* and the smegma bacillus, but stains more readily and is decolorized more quickly than the *Bacillus tuberculosis*. The bacillus is found in all the primary lesions of leprosy as heretofore stated, but is not necessarily present in the secondary trophic lesions of nerve leprosy or in secondary inflammatory effusions. A brief consideration of the pathology of the primary lesions will suffice.

Firstly, the leproma: the young leproma, upon section shows a smooth white glistening surface; when older, the cut surface presents a brown tint and the nodule may become harder, as the result of fibroid change, or softer when due to degeneration. The leproma differs from the granuloma of tuberculosis in being well supplied by blood-vessels, never undergoing caseation and, according to Hansen, contains no giant cells. This change in color to a well-defined brown is due to a number of brown granular bodies called "globi," in which Hansen says the bacilli have perished and become granular. As in other granulomata, the principal changes in the leproma are found in the corium; here the morbid process begins about the vessels, glands, and follicles. The blood-vessels are narrowed by cellular infiltration, and hyperplasia in their external and middle coats. An infiltration of the various layers of the skin may now take place, extending upward to the epidermis and downward to the subcutaneous tissue, which may become diffuse or nodular, and is composed of plasma cells, connective tissue cells, the characteristic lepra cells, and occasionally giant cells. The lepra cells are large ovoid cells, containing bacilli in clumps, held together by mucoid material. Early in the process the glands and follicles of the skin, through infiltration and hyperplasia of the cells, undergo a degeneration, followed by complete destruction and disappearance of these structures. The changes in the epidermis are secondary and the hypertrophy in the rete mucosum, the result of irritation and pressure from below, is followed later by atrophy, ulceration, and complete destruction. All throughout this infiltration the bacilli are very numerous, and a moot question, much discussed, is the relation of the bacillus to the lepra cell. Unna says they lie free in the lymph spaces and are never found in the cells. Leloir holds that some of the bacilli are free, while others lie within the cell. Hansen maintains that the bacilli are almost invariably included within the cell.

In the anesthetic form of leprosy the early pain and hyperesthesia are produced by the formation in the peripheral nerve sheaths of nodules of proliferative connective tissue which contains the bacilli. Later degeneration occurs, followed by anesthesia, as the result of increased pressure. Limited areas of sensation are retained where some of the nerve fibers have escaped pressure. Woit found that the cutaneous filaments of the peripheral nerves were degenerated, while there was little or no degenerative change in those filaments supplying the muscles, that the changes in the branches of the sensory nerves were ascending trophic degeneration, and that the degenerative nerve processes spread over the periphery, excluding entirely a central origin.

Treatment.—A large volume might readily be written upon the treatment of leprosy, but this would serve no useful purpose, except to exploit a long series of failures. So far as known all of the alleged cures have failed, when merely the test of time has been applied to them.

In the annual report of the Bureau of Health of the Philippines, 1904 and 1905, Dr. H. Brookman Wilkinson, physician in charge of the San Lazaro Hospital, reports a cure of one case of leprosy by the application of the *x*-rays in the following words: "There is absolutely no doubt that at least one case, No. 5, of genuine leprosy has been cured by the application of the *x*-rays." Chief Quarantine Officer Heizer, who is likewise the Health Officer of Manila, P. I., in the report of the Public Health and Marine Hospital Service, dated May 18, 1906, states under the heading leprosy the following: "The application of *x*-rays in two cases of leprosy treated at San Lazaro Hospital resulted in a complete disappearance of the leprosy bacilli, as far as could be determined by the microscopical examination of skin scrapings taken from former lesions, for a period of over six months. Examinations made of both patients three weeks ago again showed leprosy bacilli to be present. In view of the fact that these persons were confined with other lepers, it is not known whether they became reinfected or whether they simply had a relapse."

Unna of Hamburg has recently reported cures alleged to be due to the use of some preparation of mercury, but the crucial test of time has not been applied as yet, hence judgment is delayed. It is thought, however, that medical men who seek for success in the treatment of leprosy would do well to give up the attempt of curing a systemic disease of such well known character as this is through the medium of local applications of whatever kind.

The writer doubts exceedingly as to whether a cure will ever be found for leprosy, and certainly not till the biology of the bacillus has been thoroughly worked out, and our knowledge has been

increased relative to its life history. Until this is done segregation of lepers and isolation of children of leprous parents are the preventive measures which will give the best results.

THE SCOPE AND VALUE OF THE SANATORIUM IN THE ANTITUBERCULOSIS MOVEMENT.*

By HERBERT MAXON KING, M.D.,

LIBERTY, N. Y.

The rôle of the sanatorium in the antituberculosis movement may be considered from three more or less distinct viewpoints. First, from that of its relation to the cure of the disease as it exists; second, from that of its educational value in the community at large, and third, from that of its relation to the study of the various phases of the disease and its complications.

Before entering upon a discussion of these three relations in which the sanatorium stands to the crusade against tuberculosis, it may be well to inquire just what the sanatorium is. Notwithstanding the prominence which has been given to the subject in recent years, the most hazy, and often erroneous ideas, still exist, not only among the uninformed laity, but even among a considerable proportion of medical men as well, as to the combination of conditions, which make up the tuberculosis sanatorium. In a broad sense, any health resort is a sanatorium, and in such wise, as applied to tuberculosis, it is of course correct to refer to whole districts as sanatoria, as for instance Davos, Arosa, and St. Moritz in Switzerland, Saranac Lake, Asheville, Colorado Springs, Liberty, etc., in this country. However, the term is now better understood to refer to special institutions devoted to the care, treatment, and education of tuberculous invalids.

Of these there are two classes—the open and the closed sanatorium. The former comprises such institutions, public or private, as open their doors to patients bringing with them their own methods of treatment, or employing as physician whomsoever they will, and, while there is not infrequently in such establishments a resident house physician, he is without authority, and is usually employed to meet emergencies only. Thus it follows that often of two patients occupying adjoining apartments in an institution of this character, one may be found adhering closely and conscientiously to an ideal régime, while the other may be doing quite the contrary. Obviously, therefore, such institutions can scarcely be considered as more than medical boarding houses. They can have no educational value worth mentioning, and can offer no advantages for scientific investigation.

The "closed" sanatorium, on the other hand, is under the absolute government, so far as the treatment of patients is concerned, of its medical officers. It is here, and here only, as I shall have occasion presently to illustrate, that we find that system, discipline, and method essential to the best results. Under such conditions not only is the effect of treatment more certain, but, through constant demonstration of its value and the comparative reliability of its statistics, the sanatorium carries an incomparable educational influence out into the community at large; and finally, as I shall later endeavor to point out, more especially we find in such an institution both the material and the facilities for scientific investigation into the causes, nature, and treatment of the disease.

For the present purpose, therefore, I shall use the term sanatorium in its most restricted sense, as applied to the "closed" institution for the treatment of tuberculosis, under the exclusive medical government of its resident staff of physicians.

The sanatorium must necessarily restrict the admission of patients to such as give fair promise of material improvement, or else it inevitably degenerates into a home for incurables, and utterly destroys its *raison d'être*. Failure to comprehend the necessity for preserving an unsentimental adherence to this principle is the cause of much misunderstanding on the part of outside physicians and an emotional laity. For similar reason the sanatorium is often misunderstood, and more or less bitterly criticised for discharging a patient because after fair trial the latter shows no response to treatment, thus giving rise to the unjustifiable idea that the chief, if not the sole, object of the sanatorium is to make a fine show of statistics.

It must be borne in mind that the sanatorium is an institution whose chief function is to restore health so far as it is possible to do so, but that the possibilities in this direction have their limitations, and that when these limitations have been reached in individual cases, it becomes the duty of those in charge to substitute for such cases others whose condition justifies admission. This is especially true of State and other charitable sanatoria whose applications for admission far exceed the capacity of such institutions, and where the greatest good to the greatest number is the object sought.

In a word, the sanatorium is an institution intended to provide for the tuberculous invalid, who is susceptible of cure or improvement, the most approved means for combating his disease and restoring his health. Such institutions do not necessarily depend upon special climatic advantages, nor upon specific methods of treatment, though both of these may often serve as valuable assets. Their chief advantages and paramount therapeutic value, however, lie in a carefully-studied régime and the superior facilities which they offer to individualize systematically the treatment of a considerable number of consumptive invalids.

Having now, I hope, reached a common ground upon which we can all agree as to just what the sanatorium is, let us consider its scope and value in the present widespread movement against tuberculosis.

I have pointed out that this relationship may be considered from three points of view, of which let us consider, first, that of its therapeutic value. It is no doubt true that many tuberculous invalids recover health outside the precincts of the sanatorium, and it is equally true that failures are not uncommon within those precincts. But I must contend, notwithstanding, that when success attends the struggle in the former case, it is very largely a matter of chance. It must indeed depend upon a no less happy than rare coincidence of superior intelligence on the part of the patient, wise judgment on the part of the physician and friends, and a fortunate choice of environment, a combination which I am sure you will agree is not often found. Whereas failure to succeed under the conditions which prevail in a well-appointed sanatorium may be ascribed to inherent causes beyond our ability to control in the present state of our knowledge, and these failures in no wise weaken the argument in favor of the so-called sanatorium method.

The individual who for the first time learns that he has developed tuberculosis is in the vast majority

*Read at the Sixth Annual Conference of Sanitary Officers of the State of New York, Syracuse, October 24, 1906

of cases shocked, and to some extent demoralized. He does not necessarily *feel* sick, and is often resentful of the diagnosis. Very naturally he has little or no information on the subject of the disease or its treatment, and the suggestion of a sanatorium arouses a storm of protest. Thus, at a time when he is most in need of special instruction and vigilant skilled supervision, he compromises with the situation, and more often upon the advice of some well-meaning but misguided friend than upon that of his physician, he seeks the open health resort, where upon his own initiative he consults a physician or not.

Of course, he carries with him ideas, more or less fixed, concerning the value of climate, sunshine, open air, and food in the treatment of his disease, and he proceeds to apply these elements of treatment according to his imperfect judgment, usually calling upon the physician whom he has selected more with a view of taking a periodical account of stock, as it were, than with that of studying his mistakes and the means of avoiding them.

In the open health resort one sees innumerable instances of this kind—patients who for any one of a dozen good reasons should be in bed, riding horseback, climbing mountains, playing golf, gambling, drinking, or indulging in what would, under other circumstances, be perfectly innocent and rational amusements, but which under the circumstances can only fall into the category of blunders and vices. Or, what is even more shocking, one is forced to see—usually when it is too late to remedy—instance after instance of the consumptive, whom care would have given fair promise of cure under suitable conditions, falling a victim to the allurements of the patent medicine and the charlatan.

There is a perfectly natural, though none the less fatal, tendency on the part of the afflicted to choose at almost any risk a "short cut" to health in preference to the longer but more rational avenue—a tendency to combine the maximum of pleasure and comfort with what is at best a difficult struggle. It is one of the hardest lessons that the consumptive has to learn that a cure of his disease cannot be attained by way of the primrose path—that it involves sacrifice of much perhaps that he deemed essential to his happiness, or even to his tolerable existence, and that these sacrifices must be made voluntarily, and even enthusiastically, if he hopes to make them bear fruit.

In this summing up of the relative merits of sanatorium treatment of tuberculosis, I am ever reminded of an address delivered by Prof. Clifford Albutt at the British Congress of 1901. In the course of this address, Prof. Albutt, speaking of the sanatorium method, says: "The method was worked out in a sanatorium created for the purpose; it has been tested and perfected in sanatoriums, and, if now it can be carried on outside a sanatorium, which is not too readily to be admitted, this is so only by bringing the skill and the conditions of the sanatorium into the home. I should look with little confidence on the home treatment of a phthisical patient by a physician unversed in the practice of the sanatorium, and by a patient who had not had at least a month's training within its precincts. It is, as it were, to tell a boy at home to read his Cæsar and his Xenophon, a little Euclid and algebra, to pat him on the head, bid him be good and industrious, and promise to call in a week or ten days to see how he has got on."

This, it seems to me, is the whole matter in a nutshell. The youth who studies at home undoubtedly has a better time of it than does he who takes his place in his class at school, and has constantly over him a competent instructor to teach him when, how, and how much to study, hears his recitations, commends his successes, and checks his mistakes. But in the end it is inevitable, except in rare instances of individual devotion, which youth best succeeds. To my mind this analogy is quite to the point.

As for bringing sanatorium conditions into the home, that, of course, can be done, but it means converting the home into a sanatorium. He who is fortunate enough to be unhampered by questions of economy may do this, taking with him to such climate as shall be selected his nurse or his physician, or both. Assuming that the latter have a sufficient acquaintance with, and experience in the method, and that the patient yields obedience and cooperation, the results perhaps *may* be equally good. But the proportion of consumptive invalids so situated as to make such a procedure practicable is so small that this alternative may be left out of present consideration.

There is, however, another phase of the subject which may not be ignored. Tuberculosis, even in its earlier stages, is not susceptible of a cure under the most ideal conditions within a period of a few weeks. It has been demonstrated that an incipient lesion not larger than a few centimeters in diameter, and well circumscribed, requires for its eradication not less than two years, although the patient may to all appearances be perfectly restored to health in a much shorter period, and, as the combined capacity of all of the sanatoria in the country represents but a very small fraction of the number who have the disease, it is obvious that, however desirable it might otherwise be to keep patients in the institution until a cure be effected, as a matter of fact such a course is impossible.

In Germany, conscious of this condition, public sanatoria restrict the term of residence to a few weeks or months at most, and rely upon the educational features of this term of residence to effect a cure after the patient has left the institution. From the standpoint of the individual patient there is no doubt that this plan is relatively less satisfactory. For the tendency to relax that self-control, which is so necessary to success, together with the many temptations which surround the idle individual who is, so to speak, but unconsciously sick, combine against his welfare, and often undo the work so well begun in the sanatorium. Nevertheless, under existing conditions, it is the only practicable recourse left to the charitable and public institutions of this character.

It is obviously more desirable from every point of view to give *all* cases a fair start in the cure, and an education in proper self-care and the protection of others, than it is to carry from two to five per cent. of the tuberculous poor through the whole fight, leaving the other ninety-five or ninety-eight per cent. to "go by the board," so that, while their statistics must necessarily suffer thereby, the broadest scope of usefulness and the highest function of such institutions will be best developed when the term of residence is restricted to a few months. At the same time I am of the opinion that it is safer to err on the side of too long a residence rather than on that of too short a one. As a matter of fact, we are, and for some time shall continue to be, for one reason or another, obliged to care for a considerable proportion of these patients at their own homes. But I still contend that wherever the choice is possible it should be in favor of treatment in the sanatorium.

Let us now examine into the rôle of the sanatorium from the view point of its educational value to the community at large. This relationship presents itself in three phases: (*a*) The educational effect upon the immediate community in which the institution is located; (*b*) The educational influence exerted upon the distant communities, from which patients are recruited, by the latter upon their return to their homes, and (*c*) the educational influence of published statistics of sanatoria.

The establishment of a sanatorium in a locality is in a large sense an indorsement of the advantages of such locality for the treatment of the tuberculous invalid, and many patients, who for various reasons do not come directly into the institution, soon flock to the neighboring hamlets for the purpose of availing themselves of these advantages. Thus the sanatorium becomes an object lesson, the influence of which extends far beyond its own immediate precincts. Its salient features and its methods are observed, studied, and applied as far as possible, and those who directly and indirectly thus benefit by its treatment far outnumber, as a rule, those whom its capacity makes it possible to entertain as resident patients.

It would be comparatively difficult to induce an uninformed patient to put in practice some of the simplest and most necessary features of the sanatorium régime on the strength of the advice of an individual, but when that patient observes that such features are authorized and enforced in the practice of the institution, he acknowledges the authority, and, although he may not at the moment understand the rationale, he will usually lend his cooperation. In this way the sanatorium has a direct influence on the prevention of the spread of the disease among both the native population and the healthy sojourner in its vicinity. It has not, of course, the authority without, which it has within its own precincts. Nevertheless that its teachings extend beyond its boundaries is evidenced by the contrast in hygienic conditions prevailing on the one hand in a popular health resort where there is not a sanatorium, and on the other in a health resort which has grown up around a sanatorium.

As for the influence exerted by cured, arrested, or even improved ex-patients upon the communities in which they live, it is so commonly observed today that it must be conceded by any one whose attention has been drawn to the subject, although it is not always attributed to the sanatorium.

Let me cite an instance to illustrate what I mean. In a certain northern manufacturing town a year or two ago quite the sensation of the winter was created by a young woman who had built an outside sleeping porch and occupied it through the whole winter. The local newspapers took it up, of course, and made it serve for columns of reading matter with illustrations, not only on the subject of sleeping out of doors, but as well upon the whole régime of the sanatorium in which the young woman had been treated and educated. A great deal of interest was manifested in the community, which culminated in a local antituberculosis crusade and the organization of a society to disseminate knowledge along that line. It is too early to predict what the actual effect upon the vital statistics of this community will be as a result of the movement, but it is safe to say that it will be favorable.

Now, I do not say that such a movement might not have otherwise developed in this community, but I do contend that the example of sanatorium methods which this young woman introduced was the greatest possible stimulation to that movement. It not infrequently requires a sensational illustration to give an impetus to the most needed reforms.

Even the patient who has made no improvement in the sanatorium returns to his home possessed of the knowledge which his institutional training has given him, and which enables him to extend the gospel of improved hygiene throughout the community in which he lives. It is a point which, it seems to me, should be brought to the attention of every sanatorium patient before his discharge, that, upon leaving the institution, he carries with him a substantial influence for good which it is his duty to exercise in the cause of prophylaxis.

Finally, in this relation we have to consider the influence of the published statistics and other publications emanating from sanatoria upon the community at large. From the statistics the public learns that a considerable proportion of consumptive invalids recover health more or less completely, and are enabled to return to their homes and become useful members of society. It is also demonstrated beyond peradventure by these statistics that the earlier the disease is recognized and brought under treatment the greater is the chance for getting it under control. One cannot, I think, examine the statistics of the sanatorium without being inspired with a hopefulness of view regarding the future of phthisio-therapeutics.

The annual reports of most large sanatoria are widely distributed, and there is no doubt that in the majority of cases they excite a lively interest among those to whom they are sent. That these reports have a very decided educational value is almost certain. They lead to inquiry and often to investigation, which, by throwing light upon the whole subject of tuberculosis, cannot fail to be advantageous to the antituberculosis movement.

I need hardly more than refer before this audience to the infinite amount of good to the cause which has come from the publication of the *Journal of the Outdoor Life,* and, while this is not, strictly speaking, a sanatorium publication, it emanates from a sanatorium, and the spirit which inspires it is the sanatorium spirit.

In this connection, I must call attention to another instructive and certainly valuable feature of the sanatorium, and that is the demonstration which it affords of the fact that a large number of tuberculous invalids may dwell together as a community without danger of propagating the disease among their healthy coresidents, providing proper precaution be observed. Without being so generally recognized, I think this is one of the greatest and most needful lessons which the public at large can learn from the experience of the sanatorium.

I am sure that a more general emphasis of this very comforting fact would aid in no small degree the present crusade, and would do much to counteract the many deplorable effects of what has been aptly referred to as "phthisiophobia." In a word, then, the sanatorium demonstrates to the community at large that tuberculosis can, in a large measure, be cured; that in many cases not susceptible of a cure a useful life may be indefinitely prolonged, and that under suitable precaution the proximity of diseased individuals is not a menace to public health.

And now I wish to say a word regarding the rôle of the sanatorium in its relation to the study of the disease itself and its complications. This occasion does not permit me to consider this phase of the subject exhaustively, but one or two points there are which, it seems to me, should be brought out. With all that has been brought to light regarding tuberculosis since Koch's great discovery of the tubercle

bacillus, there remains much that is obscure and much that has so far eluded investigation as to the etiology and natural history of the disease, and undoubtedly much yet to be learned as to its treatment.

There are also many questions of metabolism which have a direct bearing upon tuberculous diseases, and which are at present only imperfectly answered. The problems thus suggested must, it is true, be largely worked out in research laboratories which may or may not be associated with sanatoria. But many of these will require for their complete solution a considerable amount of clinical material, which is not, and cannot, be available outside the precincts of the sanatorium. Here is unquestionably a field of usefulness, which so far has been but partially developed, but which must have a very decided value in future investigations along this line.

The sanatorium is not alone a school for the patient, but quite as much a school for the physician. Every year brings forth new suggestions and new discoveries, or old ones dressed up as new, as applied to tuberculosis, and the crucial test of the value of these can be made more authoritatively in the sanatorium than anywhere else.

Both in the laboratory and in the examining room of every sanatorium worthy the name data are constantly accumulating, which must have, and does have, a very decided influence and value in the treatment and prevention of the disease, and this must continue to be the case until such time as our whole conception of tuberculosis shall be revolutionized.

Finally, then, to sum up in a word:

The sanatorium (*a*) offers the tuberculous invalid the most practical, indeed the *only systematic*, method of fighting his disease and acquiring hygienic education in its prevention; (*b*) it is a most valuable educational factor, not only in the immediate community in which it is located, but to a very great extent in the community at large, and (*c*) it has a definite and important place, which can scarcely otherwise be filled in the study and investigation of the disease and its complications.

In these three relationships, then, the sanatorium possesses a scope and value of vital importance in the present great antituberculosis movement, and I can but believe that whatever the future may have in store for it, the sanatorium must always hold a place, and a vitally important one, in this great movement.

PROSTATECTOMY IN DIABETES.*

By JOSEPH WIENER, M.D.,
NEW YORK.
ADJUNCT SURGEON, MOUNT SINAI HOSPITAL.

THE beneficent results of prostatectomy are to-day too well known to need comment. In a former paper on "Prostatectomy Under Laughing Gas" (*Journal American Medical Association*, May, 1904) I stated that until recently the chief contraindications to the performance of prostatectomy were the dangers resulting from first, the general anesthetic; secondly, hemorrhage; thirdly, shock. "By the use of laughing gas the great objection of a general anesthetic is at once removed. If, in addition, we do rapid work, then all three of the objections are removed. A prostatectomy done under nitrous oxide in from eight to fifteen minutes is not accompanied by any dangers from the anesthetic, the hemorrhage in those few minutes is very moderate, and there is no shock."

So we have gradually been widening the field of prostatectomy under gas, and have been extending the benefits of the operation to very old men, even though they have cystitis and nephritis. We have found that if the operation be performed at two times, the bladder being opened at the primary operation under local anesthesia, then even cases desperately ill with marked general infection can be completely cured. I would refer here in passing to a patient of Dr. H. S. Stark whom I operated on three years ago. Mr. M., a gentleman of seventy-five years, had been catheterizing himself for five years and had had numerous attacks of cystitis and orchitis. He was having daily chills, high fever, irregular pulse, and severe general depression. He had to catheterize himself every two hours, and the urine contained 50 per cent. of pus. In view of the man's desperate condition, I drained the bladder for eleven days through a suprapubic incision and then removed the prostate. He has remained completely cured.

But there is one class of cases that has, by physicians as well as surgeons, been considered a *noli me tangere* for prostatectomy. I refer to the diabetic patient. Frequently have we heard doctors say that they would like to advise certain patients to have their prostates removed, but they had diabetes; and accordingly operation had been advised against. In a similar vein, Tuffier of Paris, at the recent Fifteenth International Medical Congress, said: "Neither old age nor gravity of the patient's general condition contraindicated operative treatment, but diabetes and albuminuria are to be regarded as rendernig operation inadvisable."

The diabetic patient facing a prostatectomy is, like all other patients, exposed to the three dangers above mentioned, to wit, the anesthetic, hemorrhage, and shock. Are there any dangers peculiar to the diabetic? Yes; two; first, the danger of coma, and secondly, the danger of infection to which all diabetic patients with wounds are exposed. We all know that in a certain number of cases, even following minor operations, diabetic patients go into coma and die. Even a prolonged ether or chloroform anesthesia, not accompanied by any operation, may bring about a fatal coma. Coma, then, is a danger rather of the anesthetic than of the operation. It surely is dangerous to give a diabetic patient ether or chloroform for half an hour or longer, in order to remove his prostate. The mortality would certainly be large. But if we can remove the prostate under laughing gas in about ten minutes, need we, then, fear diabetic coma? We can do still better and shorten the time of anesthesia still further by dividing the operation into two stages. At the preliminary operation the bladder is opened through a median suprapubic incision under local anesthesia. We have done this in some cases without using any anesthetic. The simple cystotomy can be done rapidly and is not very painful. After a few days the prostate can be removed through this incision under gas in a very few minutes. In a case of Dr. Dinkelspiel's the operation was done in two sessions on account of active hemorrhage. The removal of the prostate at the secondary operation required less than two minutes. We have on several occasions noticed that the gas anesthesia can be discontinued for a few minutes during the operation. Sometimes we have requested the anesthetist to stop giving the gas as soon as the bladder was opened; that is in from three to five minutes. During the

*Read before the Metropolitan Medical Society of New York, November 27, 1906.

actual shelling out of the prostate it is not necessary for the patient to be fully anesthetized. The retching of the patient when coming out of the anesthetic is often a help at this stage of the operation. As no ligatures or sutres are employed the patient need not be under the anesthetic after the bladder has once been opened. Need we fear diabetic coma under such conditions?

Regarding the danger of wound infection, it can, we think, be reduced to a minimum by the preliminary incision and drainage of the bladder. This can be combined with the administration of urinary antiseptics, both before and after operation, and daily bladder irrigations. In one nondiabetic case we allowed eleven days to intervene between the opening of the bladder and the removal of the prostate. Following the prostatectomy continuous bladder drainage is kept up until the urine becomes clear. Then the tube is removed, and thereafter the bladder is irrigated daily, at first through the wound and later through the urethra.

Regarding the urinary antiseptics, urotropin is probably the best to give before the operation. As soon as the wound has been made, it should be discontinued, as it frequently causes a slough to form even in nondiabetic cases. We have made it a routine practise to give salol and benzoic acid in half gram doses three times a day during the entire after-treatment, and we have been gratified with the results.

A word should be said in regard to antidiabetic diet. When the surgical disease is the result of the diabetes, as in cases of gangrene, a strict diet is probably more indicated than in the class of cases under consideration. Moreover, we must not lose sight of the fact that we are dealing here with men of advanced years, who mostly stand the diabetes very well. Further, these old men generally come to the surgeon after they have had repeated attacks of cystitis. The general condition, at least in the cases we have had, has been none too good. So it would seem to be questionable whether we ought to put these cases on a strict diet before the operation. Their nutrition would suffer, and though we might be able to reduce the percentages of glucose in the urine, we would be dealing with a two-edged sword. There is no objection to a moderate antidiabetic diet during convalescence, but it probably is not necessary. One of our patients was put on a strict diet after operation and the glucose disappeared for two weeks, but later reappeared. In a recent case, on the day of operation the urine contained three and two-tenths per cent. of glucose besides diacetic acid. The old gentleman of seventy was not restricted as to his diet, and the wound healed with surprising rapidity. Regarding the administration of sodium bicarbonate before operation, we can see no objection to its use, although we have not given it in any of our cases.

We have not been able to find any recorded cases of prostatectomy done in the presence of diabetes. Our text books teach that diabetes is an absolute contraindication to the removal of the prostate. The same belief is held by most physicians. And we must confess that we were formerly of the same opinion. It was only the wretched life that these old men, with their infected bladders led, that prompted us to offer them the benefits of the operation. The first one of these patients was told of the dangers of the operation, in fact they were rather exaggerated, but he declared he was not willing to continue living as he had, and was willing to take any chances. He not only made a complete recovery, but has remained cured, as far as bladder and prostate are concerned, for over three years. He still has diabetes, but at sixty-six he is hale and hearty, and a most grateful patient.

Case I.—Mr. S. S., sixty-three years old, was referred to me through the kindness of Dr. S. Breitenfeld. For several years he had had as much as one and a half per cent. of glucose in his urine. Five days before the operation, on arising in the morning, the patient, much to his surprise, was unable to pass any water. Dr. Breitenfeld was compelled to catheterize him regularly thereafter. Catheterization was painful, and was accompanied by some bleeding. The finger in the rectum revealed a large, very tender prostate. The urine was acid, specific gravity 1034, containing a trace of albumin, one per cent. glucose, and many red blood cells. Operation on September 4, 1903, under laughing gas. The bladder was opened through a suprapubic incision and the prostate removed in one piece. On account of the diabetes it was deemed well to shorten the anesthesia to a minimum. Accordingly no sutures were employed. A rubber tube was introduced into the bladder, and the wound was strapped with zinc oxide plaster. The entire operation lasted eight minutes. The prostate was as large as an orange, soft in consistency and the prostatic urethra passed through it near its anterior surface. During the first three weeks as much as eight-tenths of one per cent. of glucose was frequently found in the urine. The man was put on a strict diet, and the glucose disappeared for a time. Sounds were passed at regular intervals. The wound healed slowly but steadily, and the man was able to go home with a small sinus, on October 21, 1903. After leaving the hospital the glucose reappeared in considerable amount, and probably delayed the healing of the sinus. The man was again put on a strict diet, but the glucose persisted, although in smaller amounts. Two months after the man left the hospital his wound was completely healed. He could hold his water two and a half hours in the daytime and six hours at night. There was only a dram of residual urine. It is now over three years, and the man his remained in the same excellent condition. This is, we believe, the first case of prostatectomy done on a diabetic patient. The result was certainly gratifying.

Case II.—This was a patient of Dr. Khodoff's. The doctor had frequently found glucose in the urine. For full particulars of this case the author would refer to his former paper on prostatectomy under nitrous oxide, referred to above.

Case III.—Mr. S. L., seventy years old, was referred to me through the courtesy of Dr. Isadore Cohen. At the age of twenty-five he had an attack of pericarditis, lasting three weeks. At the age of forty-eight he had an attack of dengue. For the past three years the patient had had frequent attacks of malarial fever. For over twenty years he had had some difficulty in urinating. Fifteen years ago he had been told that he had some prostatic hypertrophy. Three years ago the patient began to be troubled with slight incontinence of urine. The urine would begin coming in small drops, with no sensation. This condition gradually became aggravated. During the three weeks prior to the operation there was a constant desire to urinate, accompanied by a burning sensation in the bladder, and dribbling of urine. During this time the patient had to be catheterized at regular intervals, although he was able to pass a little urine voluntarily. His appetite became poor, he suffered from insomnia, and lost weight. There were twelve ounces of residual urine. The urine contained 3.2 per cent.

of glucose, diacetic acid, many pus cells and a few red blood cells. Operation on July 12, 1906, under laughing gas. The bladder was opened through a suprapubic incision and the prostate shelled out in one piece. There was very little hemorrhage. A few sutures were introduced into the fascia and muscles, and a drainage tube left in the bladder. The entire operation took ten minutes. The prostate was the size of a large egg, and the urethra ran through its center. Three days after operation the man sat up in a chair. Eight days after operation the tube was removed from the bladder and a catheter inserted through the urethra and left in place. Three weeks after operation the man began to pass small quantities of urine voluntarily. A few days later he left the hospital. A small abscess in the left testicle was the only complication. The patient recently remarked that he was passing his urine better than he had for twenty years. During the convalescence the urine frequently contained more than three per cent. of glucose, together with diacetic acid. However, we did not restrict the diet, and yet recovery was rapid and continuous.

The cases we have reported are few in number. My apology for presenting them rests in the importance of the subject and in the absence of other reported cases. If we refuse these poor old men the benefits of operation, we are condemning them to an existence, the misery of which can only be appreciated by those who have seen their suffering. There are few more pitiable pictures than that of these old men who catheterize themselves day and night, sometimes as often as every hour in the twenty-four. Sooner or later they infect themselves, and then their misery is complete. The writer had this picture in mind when he decided to publish his cases, in the hope that it would help to awaken interest in a somewhat neglected corner of the brilliant field of modern prostatic surgery.

1001 Madison Avenue.

THE ROLE OF SUGGESTION IN THERAPEUTICS.

By WILLIAM BURGESS CORNELL, M.D.,
BALTIMORE, MD.
ASSISTANT PHYSICIAN TO THE SHEPPARD AND ENOCH PRATT HOSPITAL.

Specifically, suggestion or suggestibility, following Dubois' phraseology, indicates that faculty of mind which permits anyone to be persuaded, by no matter what process, of the existence of a fact, of the justice of an idea, or of the excellence of a determination. Suggestibility then is a function of mind, and must be therefore coeval with it, and qualitatively and quantitatively variable with it, in respect to mental development and physical environment. We are dealing with a quantity quite difficult to gauge which enters our daily lives, colors our sensations, shapes our actions, and creates illusions which enter into our mentality consciously or subconsciously, and against the influence of which we have so much difficulty in defending ourselves, try as we may.

The existence of this mental factor, as well as the fact that it could be used to influence the thought and conduct of an individual, was undoubtedly recognized in the earliest times. We trace it in the religious rites of Egyptian priests, it was appreciated and practised by Christ, Mohammed, and other founders of religions, as well as by their apostles and disciples. Objectively we can see the important participation of suggestion in such things as the belief in miracles and the performance of wondrous cures by laying on of hands, etc. In the Middle Ages suggestibility and its correlates, credulity and superstition, reached a high degree of development, due on the one hand to the enthralling influence of the church, and on the other to the repression of learning and its moulding to conform with the existing religious dogma. Consequently most of the evidence demonstrating the extent of popular suggestibility was of a religious nature, for example the crusades and the furor which swept over Europe which preceded and inaugurated the movement, pilgrimages to places of special sanctity, certain religious rites and ceremonies, cures by divinely gifted persons, by laying on of hands, etc., blessing of places and objects, consecration of water, etc., etc. But many were nonreligious, such as cures by the King's touch and the belief in charms and amulets. Further the working of suggestion may be seen in the occurrence of dancing and gyratory manias, epidemics of chorea and hysteria, witchcraft, and the practise of the Black Art. The study of all the manifestations of suggestion form an interesting part in the history and anthropology of all peoples. To trace its numerous ramifications would be almost an endless task, and would lead us too far afield in our subject. That the primitive credulity, suggestibility, and superstition as well have been handed down into the mental life of to-day abundant examples will show. We find it often existing unmodified by social evolution and untouched by the progress resulting from education and general enlightenment, although for the most part it has been considerably influenced by these factors. Even to-day pilgrimages are made to Jerusalem, Mecca, Lourdes, Holy Hill, and other shrines, and remarkable benefits and cures are obtained. A belief in the efficacy of consecrated articles, relics, etc., and even in exorcism and magic still persists in the minds of many.

Newer innovations and modifications have sprung up. The power of suggestion plus credulity has brought into prominence such people as Blavatsky, Mary Baker Eddy, and John Dowie, and have enabled them to amass followers and to found Theosophy, Christian Science, and Zion City. To this class also belong other isms, such as mind reading, telepathy, and spiritualism. To this same influence the spread and prevalence of fads of late years is due.

Especially characteristic in America is the growth of the patronage of patent medicines and of the advertising specialist with his rheumatic rings, electric belts, and various other noxious and innocuous medication. Quacks, fakirs, and charlatans of all kinds, medical and nonmedical, everywhere abound, and in their various ways utilize the power of suggestion. In all these things whatever success is achieved (and often startling it is) and whatever benefit the client receives, the common basis of it all is suggestion.

I have endeavored to sketch a brief review of what this mental attribute has produced for good or for ill as it has steadily evolved, pursuing its course undirected, its exact psychological nature for a long time undefined and unexplored.

It would be interesting to know at just what point suggestive influence was first used by the fathers of medicine. We know that the study of medicine began in superstition, and that the crude physical and medical methods employed left na-

ture and blind faith to play the major rôle. We have seen how this influence largely became the property of magicians and sorcerers who associated with it occult doctrines and irrational methods of deception. Gradually, however, physicians began to recognize the value of this power and to avail themselves of it in the treatment of certain diseases. In point of time Mesmer, the descendant of the magnetic healers, was the first of these; his practise, however, was largely mixed with charlatanism. Shortly after him appeared Hansen. Both of these used suggestion in the form of hypnotism. Hansen did much to awaken the interest of physicians throughout Europe in the subject. But both chiefly occupied themselves in popularizing the subject by giving public performances.

It is important to note that the beginning of scientific inquiry into the thorough-going effects of suggestion began with the investigation into the phenomena of hypnotism, which was at that time still regarded as a dark power or a simple deception. It remained for Braid, Liébeault, Charcot, and Bernheim to lift the whole subject out of the realm of superstition and prejudice, and to elucidate the nature of hypnosis. These investigators placed it on a scientific basis, and showed its medical and therapeutic worth.

The first perhaps to form a clear conception of hypnosis was the English surgeon Braid, who used it in the treatment of some of his patients. About the same time Liébeault of Nancy also used hypnotic suggestion in practical therapeutics. He wrote comprehensively on the subject, and was the founder of the school of Nancy. With Bernheim and other followers he created a remarkable interest in the subject throughout the scientific world. Their investigations showed that the basis of hypnosis was a prolonged state of openness to suggestion and that nearly 90 per cent. of all individuals were hypnotizable. A view considerably different to this was taken by Charcot and his school of Paris, who held that the susceptibility to hypnosis revealed a pathological mental condition, and as such only a small proportion could be hypnotized. Both schools, however, admitted the rôle of suggestion in the State, and both used hypnosis in therapeutic practice. In the height of its vogue hypnosis was supposed to offer almost unbounded therapeutic power, but it was soon seen that it had its limitations, and the past twenty years have witnessed a steady decline in its practice. It served its purpose, however, in demonstrating its basic underlying principle—suggestion—and paved the way for a rational psychotherapy in place of a practise which smacked of charlatanism, with its mystic passes and other adjuncts, and which was often exploited unprofessionally and unethically.

Almost a century before the heyday of hypnotism Pinel expressed clearly the value of suggestive measures in the treatment of the insane, and it is he, to whom we owe so many other reforms in psychiatry, who may be considered the father of psychotherapy. Before Pinel's day physical treatment was thought the only thing of value. It was he who introduced isolation. Then with this assistance after making a psychological analysis of symptoms and etiological factors, he made an appeal to the patient's logical powers and endeavored by means of rational suggestion to lead him back to mental health. Pinel perhaps laid too much stress on the value of suggestive influence in the severer psychoses or at any rate did not specify in what groups this method was peculiarly useful, namely the psychoneuroses. It remained for a later day to demonstrate why this is so, since in the insanities we have the least degree of suggestibility while mental health represents the highest. Somewhere between these extremes lies the psychoneuroses.

For many years after Pinel physical and medical measures reigned supreme in mental medicine, and psychotherapy received scant attention. The allied medical sciences were making rapid strides; with the development of physics and chemistry came advances in physiology and physiological chemistry. Pathology and bacteriology laid bare the causal agency in many diseases and suggested a specific curative method. In the bodily diseases, where a specific medicinal treatment could not be found empiricism stepped in and the ever-widening pharmacopœia was searched for remedies, and these were supplemented by various physical measures, including electricity in different forms. Everything in therapeutics was medical or physical, and bodily ills received all the attention. In mental medicine the same empiricism was applied, and little or no benefit was derived. At this period came Weir Mitchell who, thoroughly imbued with the inadequacy of the prevalent methods in treatment of nervous and mental disease, introduced isolation, overfeeding, and massage combined with psychotherapy. His success in the treatment of the psychoneuroses is of widespread renown. In this system suggestion was considered of secondary importance to isolation and overfeeding and certain other physical methods.

Practically all cases of the psychoneuroses were formerly subjected to the same treatment, but transition to a pure psychotherapy has taken place. Foremost of those to herald its advent was Dubois of Berne. This physician has gradually done away with hypnotism, electricity, hydrotherapy, and other physical methods, as well as medicines in the treatment of the psychoneuroses, and relies on suggestion alone, reserving only for special cases subsidiary isolation, overfeeding, and massage. To quote from him, "I have daily to prove the inefficacy of physical methods and the dangers to which they subject the patient." His method is to appeal directly to the reason, and by logical means to suggest how an amelioration or cure of the symptoms may be obtained. The patient is very frankly taken into the confidential relation and the psychic nature of the trouble revealed, and from rational autosuggestions, based on a philosophical view of life, a cure results which is often startling in its rapidity. The patient is often cured from the moment he believes he will be cured.

Unfortunately a cure does not always result. Among the psychoneurotics cases are found which are intractable to persuasion. These are often cases in which the disease has long existed and the resultant psychic trauma is beyond eradication. Nor do all the cases cured remain well; relapses are of common occurrence. Psychotherapy is not a specific, but in the psychoneuroses it affords the best and quickest aid we have in our armamentarium of to-day. It would be an inestimable boon to mankind if all mental diseases could be cured by mental methods. In the face of organic disease of the brain, such as paresis and arteriosclerosis, and in dementia præcox and manic-depressive insanity, psychotherapy is powerless to alter the pathological process, yet

even in these severe conditions a judicious use of suggestion may prove ameliorating. The fundamental causes of these diseases lie in an undiscovered country across an abyss which the sum of our scientific knowledge cannot in the least span. We are not much better off in the psychoneuroses. Of course here there is also some underlying organic change. We are certain however of some of the ground. We well know how changes in bodily states can produce corresponding changed mental states, how fatigue, poisons, and intoxications may modify psychic function, and how ether and chloroform may blot it out altogether. Just which mental diseases are due to changed bodily states, and which ones are due to intrinsic alteration of the brain itself remains for the future to divulge. Conversely we know how psychic states influence bodily function with a force even as great. It is upon this fact that rational psychotherapy is based. From exaggerated and erroneous interpretations of this same fact numerous systems have been developed which hold that mental treatment is the sole necessity in the cure of all ills, whether bodily or mental. Among such systems are mind cure, metaphysical healing, and Christian science. Since these teach the unreality of disease, the neglect of bodily symptoms, the divine origin of health, etc., and ignore the tenets of physiology and psychology they are not only essentially unscientific, but dangerous as well, as the practices which arise from them often lead to irreparable injury or fatal delay. With such cults psychotherapy has nothing to do.

Psychotherapy is of great value to the general practitioner. In this division of our profession we often find an ignorance of the whole matter, or, and very frequently too, a prejudice against the use of suggestion and perhaps not without some justification considering its not remote association with hypnotism and charlatanism. It is impossible, however, to write the history of therapeutics without considering the working of suggestion. All treatment exercises a suggestive influence. It would be a valuable undertaking to determine the actual benefits derived from medicines and other physical methods past and present in contrast to those arising from suggestion plus the repairing tendency of nature. I feel quite convinced that the latter two have played the greater rôle. I do not wish to underestimate the aims and results of experimental and physiological therapeutics based on exact scientific investigation, nor the few instances where we are already so fortunate as to possess a specific, nor to symptomatic alleviation, but I especially refer to diseases of unknown nature where empiricism rules. We often hear physicians admit the therapeutic worth of drugs in such cases when they say "we never take medicine ourselves, we sometimes give it to our friends, and always to our patients," or "medicine sometimes cures, it often relieves, it always consoles." Consciously or unconsciously we all make use of suggestion. No one will contest the importance of the personal equation of the psysician in relation to the patient. We appreciate the beneficent effect of a pleasing personality, and when this is combined with sympathy and a favorable assurance we often behold startling results. Many a patient is better as soon as he hears the approach of the doctor's steps. The addition of a well directed psychotherapy to these unconscious factors forms a most desirable combination, and would prove of use to the surgeon, gynecologist, and other specialists as well. In addition to a thorough understanding of the working of suggestion the general practitioner should be able to recognize the psychoneurosis early in its course. This would obviate many reverse or harmful suggestions, often transmitted unconsciously to the patient. Complaints of dyspepsia, heart trouble, headache, insomnia, etc., of psychogenous origin, are often mistaken for local organic disturbances and treated as such, with the result that the patient only grows worse and is plunged into a state of chronicity, when an early application of suggestion-persuasion methods would have cured him. Of course it is implied that a thorough physical examination has preceded the application of psychotherapy and the possibility of organic disturbance excluded. Suggestion is not a panacea, but there is no form of treatment in which it may not be an adjunct. Our individual peculiarities render it impossible that every one who so desires can practise a pure psychotherapy, but do not exclude every one from achieving as good results by methods more indirect, and from reaping the harvest which has often been left to the quack and charlatan.

Those who are out of sympathy with or ignorant of the principles of psychotherapy often show an attitude toward those unfortunates who suffer with hysteria or neurasthenia or allied conditions, which is hard to define but which frequently appears uncharitable, based perhaps on the assumption that the diseased condition is feigned, and hence should be treated lightly or jocosely. This attitude, often shared alike by doctors and nurses, and seen in our largest hospitals, is shown not only toward frank cases of the psychoneuroses but toward other patients who exhibit only isolated neurasthenic or hysterical symptoms. This has developed until the term "neurasthenic" is often applied as a reproach and unfortunately not always behind the individual's back. Such an attitude can result in no good to the patient. A thorough knowledge of the nature of the psychoneuroses supplemented by a like knowledge of the value and uses of a rational psychotherapy would obviate all this medical narrowness and uncharity.

The ability to minister to the mind as well as the body combines the highest qualities a physician can possess. Such men are undoubtedly too few in the great cities, where competition and its resulting mercantilism or the hurry and haste which are unavoidable in the carrying on of a large practice often cause a physician to forget his humanitarian calling.

However, we are making headway. There is light in the east. Psychotherapy is rapidly gaining ground and taking its proper place. Medical students and recent graduates as a rule know little or nothing of the psychoses, and the whole field of mental medicine is to them a *terra incognita*. Nor have they had in most instances previous to their medical work any training in psychology, and they are not to be blamed; for when we search the average medical school curriculum we find a startling paucity of instruction in all these branches. They must learn, if they learn at all, in the school of experience. Time should be saved for them in this department as in others, they should be taught. Psychology and psychiatry should receive their proper attention, and then in due order would follow instruction in therapeutic psychology.

GASTROPTOSIS IN RELATION TO HYPERCHLORHYDRIA.

By E. REISSMAN, M.D.,
NEWARK, N. J.
PHYSICIAN TO THE NEWARK POLYCLINIC

Relaxation of the abdominal muscles is the essential feature in gastroptosis or abdominal atony or enteroptosis or splanchnoptosis—all of these terms mean one and the same thing. The abdominal muscles have the function to keep the abdominal viscera in their physiological position; as soon as they become relaxed these viscera will sink down and there will be general ptosis of the abdominal organs, the stomach, the kidneys, the intestines, and sometimes the liver, the spleen, and even the uterus. It depends on the degree of the relaxation of the abdominal muscles with their fascia and tendons, or, let us say the abdominal walls, whether all the organs are concerned, and how much the one or the other is displaced. Another function of the abdominal muscles is to control the distribution of fluids in the abdomen, to regulate circulation and secretion. All forms of anomalous gastric secretion may be due to gastric atony; hyperchlorhydria, hypochlorhydria, and achylia. From observation made since the relations of gastroptosis to secretion have been studied by Rose, it appears that hyperchlorhydria is among the manifestations of the relaxation of the abdominal walls—at least in some cases. Of these relations one to the other, that is, of this relaxation to hyperchlorhydria, I could convince myself while assisting Dr. Rose in his clinic in the New York Post-Graduate

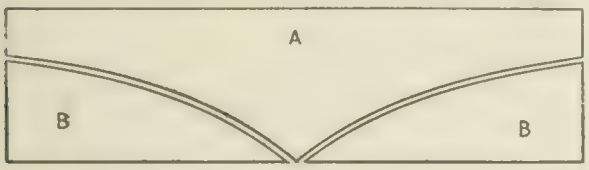

Fig. 1.—Method of cutting plaster.

Medical School. I do not know if gastroptosis, or if a splashing sound is present in all cases of hyperchlorhydria, no attention having been paid to this matter so far; but I found the coincidence in all cases which came under my observation. The symptoms of hyperchlorhydria are varied, both in character and in intensity. None of them is pathognomonic, but they are sufficiently characteristic, and, in conjunction with the results of the examination of the gastric contents, enable us to arrive at a correct diagnosis. The general appearance of the patients is commonly good. The appetite is, as a rule, good, even very good. They eat well and often, because they find relief from pain by doing so. It is only in cases in which a wrong diet, especially abstinence in eating, has been observed, that the desire for food becomes wanting. Vomiting is of rare occurrence, but when it happens the vomited matter is acrid, causing a sensation of burning or scalding in the esophagus. One symptom which is never missing is paroxysmal pain, generally two or more hours after meals; this is the time when the digestive act has been nearly completed and much of the chyme has passed out, when free hydrochloric acid is present in excess and undiluted, irritating the gastric mucous membrane through the terminals of the sensory nerve filaments.

In many cases there is burning in the stomach; this may happen a little earlier than the real pain. Some patients complain of sour stomach; they feel the acidity of the stomach in the mouth.

Eructation is a frequent symptom; constipation is the rule, but there are exceptional cases in this regard. The all-important part of the treatment is the diet. In Rose's clinic we ordered invariably the regimen laid down by Illoway in his classical treatise on Hyperacidity in the *New York Medical Journal*, 1901:

Breakfast: Milk, two hard-boiled eggs, bread and butter. Two hours later a vichy tablet in half a glass of water.

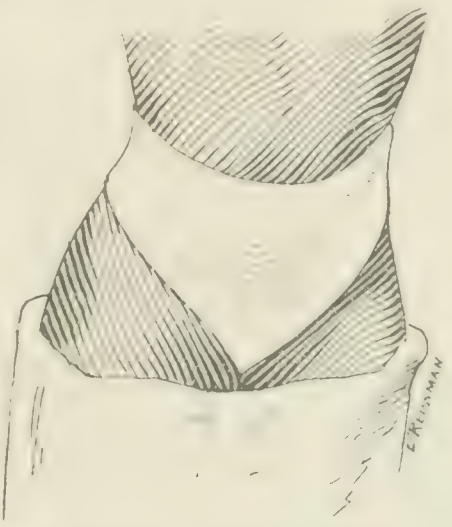

Fig. 2.—Showing mode of application of strip A.

Lunch: Chops or steak, roast beef or roast mutton, bread and water; if desired, a little potato or rice. Two hours later a vichy tablet in half a glass of water.

Dinner: A little soup, broiled fish, roast beef, roast mutton or roast chicken (only occasionally), a little potato, a small dish of some vegetable.

At Bedtime: A glass of vichy or milk, or a sandwich of cold beef or cold mutton, or cold chicken.

Forbidden: Anything ice cold or very hot, stimulants of any description, spices, tea, coffee, cocoa, all sweet things, fruit, and tobacco.

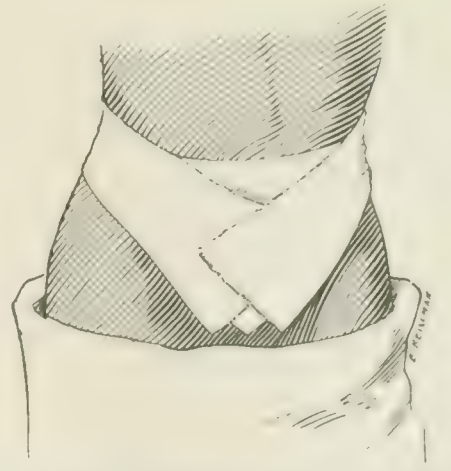

Fig. 3.—Showing mode of application of strips B, B, completing the bandage.

Against constipation a teaspoonful of Carlsbad salts in a glass of warm water before breakfast. As regards other medication, besides vichy and Carlsbad salts, we found that atropine pills of 1-240 grain, three times a day, did excellent service to relieve the pain. As a rule, they were required only during the first week, because after that time the diet alone would prevent occurrence of pain. Atropine, as is well known, has a tendency to reduce gastric secre-

tion. Strictly interdicted is vichy in syphons, because the carbonic acid gas, with which it is charged, seems to produce quite severe pains in these cases.

In order to distinguish the effects of the diet and medication alone, we desisted in some cases from relieving at once the apparent cause of hyperchlorhydria, and we found that the diet alone did not relieve the symptoms as promptly as when abdominal strapping was added to the therapeutic measures.

In every case of illness which we have under treatment our first aim must be to remove the cause if we can do so. The cause of hyperchlorhydria, according to our experience, is, at least in many instances, abdominal relaxation. This fact will be appreciated when attention is paid to the relation of abdominal relaxation to disorders of gastric secretion. It is claimed that hyperchlorhydria is a neurotic affection, but very few have yet appreciated, I believe, that gastroptosis is often the cause of nervous disturbances. The relaxation of the abdominal wall brings about morbid changes of circulation, of the distribution of fluids in the vessels, of the movements of the water in the tissues and in the cells, and, above all, in the secretory functions of the abdominal organs. We have found that all forms of secretory disorders in the stomach may be connected with gastroptosis. In all these cases of functional disorders in which we find gastroptosis, in which we can produce the splashing sound, we should first of all relieve the abdominal relaxation. No other method to accomplish this is more rational, more directly to the point, than plaster strapping; it has decided advantages over all others, and it is the only one which acts on the crosswise fibrous arrangement of the abdominal muscles. The time will come when this method will be generally adopted. The plaster used for this strapping is Z. O. adhesive plaster on moleskin seven inches wide and as long as the circumference of the waist measure of the patient. This plaster is cut into three pieces shaped as figure 1. The abdomen is shaved down to and including the symphysis and is washed with ether. The large piece is first applied, the point being placed over the symphysis and the ends meeting and overlapping in the back. (See figure 2.) The plaster should run above the crest of the ilium. The smaller pieces are then applied as shown in figure 3, and they serve as an additional support of the abdominal walls. Considerable force may be used in applying the side pieces which run from the hypogastrium over the iliac and inguinal regions and meet at the spine.

In order to guard against loosening of the plaster, care should be taken that the edges are perfectly adherent. The plaster is worn for five weeks, usually without discomfort to the patient, who, on the contrary, feels a sense of relief by the support. The composition of the plaster prevents, as a rule, any dermatitis, unless the plaster becomes loose and air penetrates.

1007 Broad Street.

Observations of Epidemic Cerebrospinal Meningitis.—G. Daddi gives us the results of his observation of cases of epidemic cerebrospinal meningitis in Florence. In the epidemic observed the disease was not of a very malignant form, as about one-half the cases recovered. The cases were limited to one single locality and to three dirty houses, although these were surrounded by other houses. In one case, accompanied by marked hydrocephalus, the bacteriological examination showed the disease to be due to the Fraenkel diplococcus of pneumonia. Of six cases treated in the hospital, five showed cocci of a globose shape, with a tendency to join into chains of two or three, staining well with aniline, and corresponding to the *Bacillus intracellularis meningitidis*. One case showed Fraenkel's pneumococcus. The bacilli were of slight vitality, dying after two or three days at most. Moisture helped to keep them alive longer. They developed at a temperature of 28° to 30° C. sparingly, best from 36° to 37° C. Hence the germs may be said to be killed by drying and by keeping them at an ordinary temperature. They show slight virulence toward the common animals used in experiments. There were no germs found in the nasal mucous membrane of five of the patients in whom it was examined. Agglutination takes place with the serum of other cases of meningitis due to this bacillus, but not with other germs. This agglutination seems to be specific, but is not found in very dilute solutions.—*Rivista Critica di Clinica Medica.*

Renal Decapsulation in Nephritis, with Report of a Case.—Henry Harris gives the history of a patient with grave chronic parenchymatous nephritis, who after being treated energetically by medical measures in the hospital for two and one-half months, was discharged much improved. This improvement was of short duration only. One and one-half months after being discharged, the patient's condition was again serious and it was necessary to readmit him to the medical ward. His second stay lasted only two weeks; at the end of that time his condition was very slightly improved. One month after this he entered the hospital for the third time in a serious condition. At the end of a month he had not improved. Bilateral renal decapsulation was then performed. Improvement was noted about three weeks after the operation. In contrast to that of previous admissions, the improvement following operation has been permanent, now lasting sixteen and one-half months and has been very positive. This improvement is seen both in the patient himself and in his urine. The daily output of urine has increased, and the urea has increased. Albumin is present only in traces, and casts are only exceptionally found. Renal decapsulation has been of value in the treatment of this case. Since these notes were written it has been learned that the patient has sailed for Canton, China, in order to take the governmental examinations for a scholarship in this country.—*Bulletin of The Johns Hopkins Hospital.*

Surgery of the Large Venous Trunks.—Doyen has made a study of lateral and circular ligatures in the surgical treatment of the large venous trunks. The lateral ligature gives excellent results in cases of slight injury of the internal jugular or axillary as in cases of rupture or of section of a branch at the point of connection with its principal trunk. The most interesting chapter from the point of view of surgical technique has to do with suture of the veins. Twice circular suture has been performed on the axillary vein when it has been almost completely cut across. Primary union was obtained, and the operation was not followed by any circulatory disturbance. Most of the favorable interventions were in cases of septic thrombophlebitis of the lateral sinus which had become infected by spread of the infection from a mastoid suppuration.—*Le Bulletin Médical*

Syphilitic Arthropathies.—Leonardo Dominici describes two cases of arthritis of long duration, localized symmetrically on both sides, with swelling, fluctuation, and spontaneous pain at night. The articular fluid was sterile and tuberculin gave no reaction. Mercurial teratment benefited them. Syphilitic joint troubles occur in both the secondary and tertiary periods. They are more frequent in the tertiary period and may occur as late as twenty years after infection. They are primarily articular, or result from gummatous formations on the articular surfaces. These arthropathies present no characteristic specific symptoms and can only be diagnosed by exclusion and by the results of treatment.—*Il Policlinico.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 15, 1906.

THE EFFECT OF SALICYLIC ACID PRESERVATIVES ON HEALTH.

ONE of the most noteworthy tendencies manifested in recent remedial legislation has been the desire to obtain a food supply free from adulteration and chemical preservatives. The agitation all over the country has assumed such proportions that a national law has been enacted to supplement the statutes in the various State codes. Among the investigations which have had a very practical bearing in prohibiting the use of chemical preservatives are those conducted at the United States Department of Agriculture on the now famous "poison squad." The effects of boric acid and borax in the food were first studied and the publication of the results of these experiments called forth numerous protests not only from interested manufacturers but also from scientific authorities in high standing. Thus Prof. Liebreich of Berlin, the well-known pharmacologist, as we have previously noted, contended that the results could not be considered as conclusive on account of the manner in which the tests were conducted, and that no danger attaches to the use of the small quantities of the chemicals ordinarily employed as preservatives. This argument has been urged with great vigor and ingenuity, but it is not conclusive, for although minute quantities would not be dangerous so far as a fatal effect is concerned, the continued use of such materials seems likely in the end to produce an injury of greater or less extent.

Salicylic acid and the salicylates have also been subjected to a series of tests similar to those conducted by the Department of Agriculture with boric acid preservatives, and the results of the experiments have been published by Dr. Wiley in a recent circular (No. 31) of the Bureau of Chemistry. There is a general consensus of opinion among medical men that salicylic acid and its compounds are very harmful substances, and the prejudice against this particular form of preservative is perhaps greater than against any other. Dr. Wiley believes, however, that there is no reason why salicylic acid should be singled out for especial condemnation, and from his experiments it appears that, although it is a harmful substance, it may be less serious in its effects than has been generally supposed. But this is no argument for the use of the drug as a food preservative. The indications for the administration of the salicylates as medicines are well established, but, as Wiley states, such administration should be controlled entirely by the medical profession; and simply because salicylic acid is well established in the Pharmacopœia and universally recognized as a remedy for rheumatism and gout, this fact should not serve as a warrant for its promiscuous use in foods, even if it were harmless. The experimental data show very clearly that this drug and its compounds exert an exciting influence upon the activities which take place in the alimentary canal, and that this stimulation leads at first to increased digestion and absorption. But the data also show that the general effect upon the system is depressing, causing the tissues to be broken down more rapidly than they are built up, and that thus the normal metabolic processes are interfered with in a harmful way. In fact, a gradual decrease in the weight of the subjects was noted, although the quantity of food was increased sufficiently to have produced an opposite effect.

The only practical conclusion which can attend these observations is that, although salicylic acid compounds given in minute doses cannot be dignified by the term poison, they are yet sufficiently injurious if taken continuously to exert a depressing and harmful influence upon digestion and the general metabolic activities of the body. As food can be preserved in an unobjectionable manner without its aid there seems to be no valid reason why it should be retained for this purpose. Its use, as well as that of other chemical antiseptics, leads to carelessness and indifference on the part of the manufacturer, for many of the processes necessary to the proper selection, cleansing, and preservation of food stuffs are thus neglected. When the harmful character of any substance which it is desired to add to food is thus established and no reason for its employment can be given except convenience or indifference, then the exclusion of such material from food products follows as a logical sequence and a hygienic necessity.

THE PATHOLOGY OF CHOREA.

CHOREA is a self-limited disease, especially of early life, occurring most commonly in the spring of the year, coincidently with, as a sequel to, or as a precursor of rheumatism. It has, by competent authority, even been designated cerebral rheumatism. The etiology of both chorea and rheumatism has not yet been definitely established, but there is sound reason for believing that both are infectious diseases having a common cause. The evidence thus far brought forward on this point, though not entirely conclusive, certainly is strongly suggestive, and it only needs substantiation before its final acceptance. Much work of a highly trustworthy character has been done in this connection by Poynton and Paine, and the former of these observers is now, in conjunction with Dr. Gordon M. Holmes (*Lancet*, October 13, 1906), able to present a report of three additional fatal cases of chorea, in which the diplococcus considered responsible for rheumatism was found in the brain and meninges, as well as in the other lesions present. With cultures of this microorganism it was possible to produce multiple arthritis and pericarditis in lower animals. Histological study of the brain and meninges revealed hyperemia, small hemorrhages, multiple thrombosis, serous exudation,

round-cell infiltration, softening, swelling, and distention of the cortical cells, with partial loss of tigroid and varying degree of chromatolysis of Betz cells, beginning chromatolysis of the cells of the basal ganglia, with slight nuclear swelling.

In one case post-mortem examination disclosed the presence of general and recent pericarditis, bilateral pleurisy, mitral endocarditis, and myocarditis. In a second case there was recent pericarditis over the posterior surface of the heart, with pericardial adhesions over the anterior surface, recent endocarditis of the mitral and tricuspid valves, and acute edema of the lungs. The third case occurred in a primipara, and it became necessary to evacuate the uterus on account of the violence of the movements. On post-mortem examination recent vegetations were found along the margins of the mitral valve.

From the evidence presented it may be concluded that the symptoms and lesions of chorea are due to the microorganisms found associated with the disorder, together with the toxins they produce, and in view of the common association of chorea and rheumatism and the identity of the microorganisms underlying the phenomena of each, it must be concluded further that chorea is in reality merely a cerebral manifestation of rheumatism.

THE DIETETIC TREATMENT OF ULCER OF THE STOMACH.

At present three principal plans of treatment of gastric ulcer are in use in Germany. The first and perhaps the most widely employed is that advocated by Leube; this is essentially a rest cure both for the body as a whole and for the stomach. The patient is kept in bed and hot fomentations, or in cases of hemorrhage an ice bag, are applied over the stomach more or less continuously, while the diet is an extremely restricted one. During the first ten days it consists of boiled milk, bouillon, and zwieback, during the following week of purees, rice and sago boiled in milk, raw and soft boiled eggs, and calf's brain or sweetbread. During the next five days scraped raw ham, scraped beef, boiled calf's foot, mashed potato, and a little coffee and tea are allowed, and during a further period of seven days, rare roast beef, broiled chicken or pigeon, macaroni and little bread are given. After this the return to normal diet is gradually managed.

The diet of Lenhartz represents a protest against this plan of under nourishment and is founded on the view that anemia and hyperacidity are not only predisposing causes of gastric ulcer but frequently retard the patient's recovery and must be combated from the first. Lenhartz therefore from the very first, even immediately after a hemorrhage, gives a concentrated albuminous diet of milk and raw eggs with sugar so that at the end of two weeks a daily allowance of 3,000 calories is reached. On the sixth day chopped meat, on the seventh day rice, and three days later scraped raw ham and butter are added to the dietary. Lenhartz and his followers claim that in this way the excess of free acid is bound and that through the more rapid gain in strength recovery is more prompt than is the case in the under-nourishment plan of Leube.

Senator attempts to combine the advantages of both régimes by supplying a dietary which is sufficiently nourishing without tending to overload the stomach. He recommends the use of a combination of gelatin, cream, frozen butterballs, and sugar. While all three of these plans have yielded excellent results there is still considerable difference of opinion in regard to their respective advantages.

Schmidt, in an article appearing in the *Deutsche medizinische Wochenschrift* for November 22, 1906, expresses the opinion that the principle of adequate feeding embodied in the Lenhartz treatment is a good one, but says that he is not ready to increase the dietary as rapidly as does this clinician. He believes that it is necessary to give the stomach rest as Leube has pointed out, but that the dietary should be increased sooner than Leube recommends by the addition of eggs, gelatin, butter, cream, sugar, and rice, but chopped meat and scraped ham should be given only with caution.

A New Method of Amputation of the Upper Extremities.

A new method of amputation of the upper extremities is described in a most interesting article by Antonio Ceci in *La Presse Médicale* of November 17, 1906. The originator of this method is Giuliano Vanghetti. Ten years ago Vanghetti conceived and put into execution this method, making experiments on chickens. He proposed to utilize muscles and tendons which remained uninvolved in the amputation of any limb, or such as were preserved in an amputation stump. He aimed to form a ring or club-shaped mass of these living tissues, which would permit the stump to communicate motion to an artificial hand more or less complicated. Ceci has recently had the opportunity of practising this method in three cases. This method, says Ceci, might well be called "amputation cinéplastique." Although Vanghetti has treated the subject in a very theoretical fashion, several of his propositions not being practical, nevertheless the fundamental idea is original and valuable, and deserves a place in the technique of contemporaneous surgery. Ceci gives a graphic account of the three cases in which he has applied the method. The first patient, a man thirty-three years old, presented himself with a recurrent myxosarcoma of the forearm with metastases to the axilla. Amputation according to this method was performed. A musculotendinous ring entirely covered with skin and subcutaneous tissues was formed. The extremity of the amputation stump was thus supplied with a traction ring to which could be applied the cord of an orthopedic apparatus. These tissues are gradually educated to perform their work. As soon as the cicatrix becomes solid, exercises of traction on the ring are practised so that little by little the patient is able to raise an increasing weight by muscular contraction of these parts of the stump. The writer illustrates his article with cuts which represent the patient as holding a lamp in his artificial hand while the arm is extended. In another cut he is represented as holding a hatchet in the same manner. Another patient is shown holding weights by means of the action of the two parts of the stump forming two traction rings which face each other. The method of amputation here described is highly original and

differs essentially in its technique from any other operative procedure.

The Opsonic Index in Pulmonary Tuberculosis.

The opsonic question is confessedly one of great intricacy, and yet indications are not wanting that it is gradually being introduced into practical medicine. Long observation, however, will be required before its limitations can be definitely determined. Some interesting statements were recently made by Crace-Calvert at a meeting of the Manchester Medical Society (*Lancet*, November 24) on the relations of the opsonic theory to tuberculous patients in sanatoria. He noted that in acute general infections the disease lasted only a short time as a rule, and there was a large absorption of toxins which caused a production of antitoxins, and hence recovery resulted. In the chronic or local infections there was a poor development of toxins with a corresponding poor production of antitoxins, and to obtain recovery it was necessary to produce more antitoxins. The readiest way of doing this was by the inoculation of toxins or of sterilized microorganisms of the disease. In order to do this with safety it was necessary to estimate a patient's resistance to the disease, and this could now be done by Wright's method of estimating the opsonic index. Crace-Calvert showed that in normal healthy persons the index was between 0.8 and 1.2, though in a series examined by him one healthy man had an index of 1.3. The index in persons predisposed to tuberculosis was probably low (though no estimations were known), and hence they sooner or later fell victims. In ten early cases examined on arrival at the sanatorium the index was always between the normal limits, and the estimations did not, therefore, help much in diagnosis. In ordinary subacute cases the index was usually about normal, probably from an absence of autoinoculation. After showing that a high opsonic index was of value, he said that it could be obtained and generally maintained by appropriate doses of a suitable "vaccine" repeated at the proper intervals. In early cases there was probably no need to inoculate, as all these patients did well with ordinary sanatorium treatment. In acute cases it was not safe to inoculate, except, perhaps, with extremely small doses, such as 1-4000th or 1-6000th of a milligram of tuberculin. When the symptoms had quieted down with ordinary sanatorium methods inoculation might help toward recovery. The further statement was made that at present the author inoculated only patients not doing well with ordinary sanatorium methods; he always estimated the index several times before beginning inoculations, and he always allowed the patients to rest one day before and three days after inoculating, so as to avoid autoinoculation.

The Causes of Postoperative Pneumonia.

At the German Surgical Congress held about a year ago the question of the etiology of the pneumonias following operations, particularly laparotomies, was made the subject of an exhaustive discussion. While, in spite of the interest the question aroused, no very definite conclusions were arrived at, in a general way the consensus of opinion seemed to be that the anesthesia did not deserve so prominent a position as a causative factor as had usually been ascribed to it. Infection by way of the lymphatic channels and the blood stream, and hypostasis were brought forward as important possibilities, though it was admitted that it was difficult to recognize pneumonia due to the two former means of origin, and the greater significance was accorded to vascular stasis. Lichtenberg, writing in the *Münchener medizinische Wochenschrift* for November 20, 1906, takes up the question from the experimental rather than the statistical standpoint, and states that even though the operators of the Breslau clinic have found that the mortality from postoperative pneumonia has been greater in cases in which local anesthesia was used than when a general anesthetic was employed, this means but little, since the patients operated on under the former conditions are usually those whose situation is already desperate, and who are therefore especially predisposed to complications. He administered chloroform, with and without the admixture of oxygen, for long periods of time—several hours—to rabbits by means of a specially devised apparatus. Some of the animals were killed immediately after the termination of the anesthesia, others after varying intervals of time. It was found that in all instances, and increasing in gravity in proportion to the length of the anesthesia, changes were produced in the lungs, in some cases resulting in typical lobular pneumonia in the course of about forty-eight hours. These changes consisted in swelling and desquamation of the respiratory epithelium and hemorrhages into the alveoli, leading to plugging of the smaller bronchi and the formation of numerous areas of atelectasis. Similar areas are also produced as the result of aspiration and of increased secretory activity. Those due to aspiration may be regarded as being already infected, the others are certainly areas of lessened resistance. While the author's experiments were protracted over periods of time that rarely come into question in administering anesthetics to human beings, and while it is not possible to transfer directly to man results obtained from a study of rabbits, the use of chloroform is undoubtedly attended to some extent by dangers of this sort, particularly since the opportunities for infection are so great in man. Whether or not it is wise to use this fact as an argument in favor of spinal anesthesia as Lichtenberg seems inclined to do is, however, an open question.

A Foreign Body in the Digestive Tract.

Although in many cases the ingestion of foreign bodies is not followed by serious results, the possibilities of an unhappy termination are sufficiently recognized to give interest to any successful method of treatment. As a rule in children the expulsion of foreign bodies is spontaneous. Montéli recently communicated to the Société d'Anatomie et de Physiologie (*Journal de Médecine de Bordeaux*, November 18, 1906) a case which came under his observation. The patient, a girl sixteen years old, had swallowed a pin. Although Montéli appreciated the fact of the ordinary innocuousness of such foreign bodies in the digestive tract, nevertheless he thought it wise to attempt to expel the pin on account of its size, three and a half centimeters, and on account of the very sharp point of the steel shank. At first he ordered the patient to eat a potato salad dressed with oil. This did not dislodge the pin. Radioscopy failed to reveal the position of the pin. The writer, upon the suggestion of Bergonié, then decided to use absorbent cotton. Bergonié had already employed this method in a similar case with excellent results. A small piece of

absorbent cotton, the size of a nut, soaked with butter, was given to the patient. It sometimes happens that a pin which has been swallowed is enveloped by the cotton and is expelled with it. In this case, however, the result was not so perfect. The patient, who swallowed the pin on Thursday, took the cotton on Friday. The stool on Saturday did not contain anything foreign, but on Sunday the stool was followed by the expulsion of the cotton. The third stool which was passed after the pin had been swallowed contained this object. This occurred on Monday morning. The pin was not enveloped by the feces and was but slightly attached to them. Bergonié suggested that perhaps the foreign body had been brought by the cotton to the neighborhood of the anus, where it was accidentally dropped. The history of this case appears to justify the reputation for good results that this method of treatment has acquired. Rabère has observed that foreign bodies, when they are expelled, are nearly always enveloped by the feces. Courtin calls attention to the merit of this method on account of its safety.

Silence as an Adjuvant in the Treatment of Laryngeal Tuberculosis.

Sir Felix Semon, in an address delivered before the Berlin Laryngological Society on the occasion of the meeting held November 16, in commemoration of the seventieth birthday anniversary of its president, Professor Bernhard Fraenkel (*Berliner klinische Wochenschrift,* November 19, 1906), took as his theme the value of complete rest of the larynx as an accessory measure in treating tuberculosis of this organ. He said that while in former years he had frequently attempted to employ the plan of insisting on absolute silence in the case of private patients, he had found it so difficult to enforce obedience to this direction that he had been obliged to abandon the effort and to restrict himself to the recommendation to refrain from speech as much as possible. Of late, however, the universal resort of tuberculous patients to sanatoria had made it possible to have recourse to this very valuable principle. Patients nowadays were apt to have a better understanding of the gravity of their condition and the necessity for giving themselves up entirely to the business of getting well, and under these conditions it was usually not difficult to induce sanatorium inmates to adhere to the rule of absolute silence. The value of the measure he considered was unquestionable, and the benefits derived fully compensated for the self-denial involved. In very advanced cases, of course, nothing could be expected; but in the earlier stages, especially when attended by inflammatory irritation, in cases of localized ulceration of the vocal cords and in the interarytenoid space, and in general infiltrations of the cricoarytenoid articulation, the plan was especially to be recommended. While the lessened activity of the parts affected no doubt would be of great advantage in all cases, a certain amount of discrimination would be desirable in carrying Sir Felix Semon's recommendation into effect. The progress made by the tuberculous patient is so largely modified by the mental attitude that it would certainly be undesirable to insist on this somewhat rigorous measure in dealing with persons already manifesting any tendency to despondency or undue introspection. The success of the sanatorium patient in refraining from all conversation would also depend largely on the attitude of his companions, and if their cooperation could be secured the deprivation would be shorn of some of its hardships. Fortunately, tuberculous patients are usually sanguine in temperament, and for such the suggestion made by Sir Felix Semon would be well worth a trial.

Prostatectomy in Two Stages.

In a recent issue we referred to an article in the *Annals of Surgery,* in which it was shown that prostatectomy might profitably be performed in two stages, the first operation consisting of simple incision and drainage, the actual removal of the gland being deferred to a later period, when the congestion had been in large measure reduced, the parts being therefore in a more normal condition. The advantages of this procedure are manifest and the method will probably become one of choice, not only in prostatectomy, but also, as Dr. Wyeth pointed out in the Medical Record of December 8, in other operations where haste is not an essential element. Such being the case, the question of priority is one of some importance, and Dr. Lilienthal, in the letter which was published last week, brings forward strong evidence in support of the claim that he is fairly entitled to the credit of having first suggested and performed the operation in question.

News of the Week.

A Society for the Suppression of City Noises.—Mrs. Isaac L. Rice, after having been successful in her efforts to restrict river noises, has undertaken the organization of a "Society for the Suppression of Unnecessary Noise." This is intended especially to protect the inmates of hospitals from the needless street noises around such institutions, though the attempt will be made to suppress in the city as a whole some of the sounds that contribute so largely to make town life the nerve-racking existence it is. An advisory board and a board of directors, each consisting of twenty-five members, are being formed from among well-known men. It is proposed to have a practically unlimited membership, the members to pay nominal annual dues to cover the cost of printing the literature which it will be necessary to scatter broadcast in the interests of the movement. Needless to say, the movement is meeting with the cordial support of the hospital superintendents and the health department, as well as of others who resent the disturbance of rest caused by the flat wheels and gongs of the trolleys, the bells of junkmen, the cries of newsboys and of street vendors, and the thousand and one unnecessary noises of our city streets.

The Walter Reed Memorial.—President Roosevelt has sent to Congress the memorial of the Walter A. Reed Memorial Association, asking for an appropriation for a monument to Dr. Reed and his associates, in recognition of their services in demonstrating the mosquito theory in yellow fever. "Major Reed's part in the experiments, which resulted in teaching us how to cope with yellow fever," says the President, "was such as to render mankind his debtor, and this nation should in some proper fashion bear witness to this fact." The plan for the monument includes not only a memorial to Dr. Reed and Dr. Lazear, but is also to contain a tablet with the names of the soldiers and enlisted men of the Hospital Corps who voluntarily submitted to inocculation, some of whom died.

Yale Medical School Requirements.—The requirements for admission to the Medical Depart-

ment of Yale University now comprise as a minimum qualification two years' work of college grade, including the subjects of inorganic chemistry, physics, and general biology. A student in Yale College may by a proper choice of subjects secure both the B.A. and M.D. in six years.

To Restrict the Sale of Narcotics to Savage Races.—Negotiations are under way to secure the cooperation of the United States and Great Britain in submitting to the Powers a treaty prohibiting the sale of intoxicants and opium among all uncivilized races. Those advocating the measure are hopeful of success in view of the anti-opium movement which has resulted in the release of China from the obligation to buy British opium and in the pronounced reform sentiment in England. The Senate has already three times passed a resolution favoring such a treaty.

Smallpox in Brooklyn.—Twelve cases of smallpox were recently discovered by the Board of Health officials in one day in negro tenements in the neighborhood of Cleveland place, Brooklyn. The entire block in question has been quarantined.

Gift to Philadelphia College of Physicians.—It was announced at a recent meeting of the Philadelphia County Medical Society that Andrew Carnegie has promised to give the College of Physicians of Philadelphia the sum of $50,000 contingent on the college raising $100,000. The money is intended for the erection of a new building for the society.

Plague Rats in Manila.—It is reported from Manila that during the past few months considerable numbers of rats infected with bubonic plague have been found in two districts of Manila, and that active operations to exterminate the rodents and disinfect the contaminated quarters have been put into execution.

Colloidal Metals in Pneumonia.—Dr. Robin of Paris is continuing his experiments on the value of the subcutaneous injection of metals in the colloidal state, and has recently reported a series of fifty-one cases of pneumonia, twenty-six of which were serious, with six deaths.

Yellow Fever in Cuba.—According to recent accounts, there are only three cases of yellow fever in Havana, and three others in the interior of the island.

Professor Eli Metchnikoff on November 30 received The Royal Society's Copley medal in recognition of the importance of his work in zöology and pathology. On the same date the Darwin medal was awarded to Professor Hugo de Vries on the ground of the significance and extent of his experimental investigations in heredity and variation.

A Portrait of Dr. H. M. Hurd, Superintendent of Johns Hopkins Hospital, was presented to the hospital by the medical staff at a dinner recently given in honor of Dr. Hurd.

Dr. A. E. Halstead of Chicago has been elected Professor of Surgery in the Northwestern University Medical School.

National Red Cross Officers.—At the annual meeting of the American National Red Cross, held in Washington on December 4, the following officers were elected for one year: *President,* William H. Taft, Secretary of War; *Treasurer,* Charles H. Keep, Assistant Secretary of the Treasury; *Counsellor,* James B. Reynolds, Assistant Secretary of the Interior; *Secretary,* Charles L. Magee; *Board of Consultation,* Brig.-Gen. Robert M. O'Reilly, Surgeon-General, U.S.A.; Surgeon-General P. M. Rixey, U.S.N.; Surgeon-General Walter Wyman, Public Health and Marine Hospital Service.

A New Medical Society.—The physicians of the Eastern District of the Borough of Brooklyn, New York, have formed a new medical society to be known as the Williamsburgh Medical Society. The organization meeting was held on Wednesday, December 5, 1906, at 90 Manhattan avenue, and forty-eight physicians were enrolled as members. The following officers were elected for the ensuing year: *President,* Leon Louria, M.D.; *Vice-President,* Wm. Linder, M.D.; *Corresponding Secretary,* Marcus J. Levitt, M.D.; *Financial Secretary,* Ed. L. Friedman, M.D.; *Treasurer,* A. Hayman, M.D. The society will meet every second Wednesday of the month.

Hospital News.—*The Jewish Hospital of Brooklyn* was formally opened on last Sunday and addresses were made by Oscar S. Straus, Abraham Abraham, Herman S. Metz, St. Clair McKelway, and others. The hospital which is to be conducted as a nonsectarian institution is situated on Classon and St. Mark's avenues and has cost $335,000. Most of this sum was raised by subscriptions of small amount. The finances were managed by Abraham Abraham, who is president of the hospital. It has 175 beds and patients are to be treated from $1 a day upward. The first patients will be received on December 17. Dr. Jacob Fuchs is chief of medical staff.

St. Catharine's Hospital.—By the will of the late Mrs. Caroline Goldbach, filed for probate in the Surrogate's Court, Brooklyn, $3,800 is left to St. Catharine's Hospital.

Beth Israel Hospital Ball.—To raise funds to meet the expenses incurred by the erection of a new wing to its building, Beth Israel Hospital is arranging for a Purim ball to be given on March 13 at Madison Square Garden. The hospital is at Cherry and Jefferson streets, and last year treated 44,000 ward patients.

Seney Hospital. — The Halls administration building of the Methodist-Episcopal Hospital in Seventh avenue and Sixth street, Brooklyn, was dedicated last week with public exercises, at which the Rev. Dr. James M. Buckley, president of the board of managers, presided. The hospital, known as the Seney Hospital, was founded twenty-five years ago by the late George I. Seney, whose gifts to the institution amounted to over $400,000. Four years ago Mr. and Mrs. William J. Halls, Jr., offered to complete the hospital at an expense not to exceed $125,000, on condition that $500,000 be raised to pay off the floating debt and bring the endowment of the institution up to $850,000. More than $450,000 having been raised, it was decided to open the central, or administration building, which has been named after Mr. Halls. The third building will probably be completed and ready for dedication within a year.

Benefit for the Sydenham Hospital.—A testimonial benefit performance for the Sydenham Hospital, at 343 East 116th street, was held on December 9 by Mr. Leo Shubert at the Lyric Theater as a memorial to the late Samuel S. Shubert.

Proceeds for Chicago Union Hospital.—This hospital received $2,000 as proceeds from the address of Senator Tillman, recently delivered in Chicago.

Presbyterian Hospital Anniversary. — The thirty-eighth anniversary of the Presbyterian Hospital was celebrated last week with appropriate exercises in the Florence Nightingale School for

Nurses, opposite the hospital. After the exercises the guests were taken through the hospital and to the new open-air ward on the roof, which is just being finished, and the advantages of the hospital's method of open-air treatment of a great many conditions were explained. The annual report of the hospital, just issued, shows that during the year 11,849 patients were treated in the hospital proper, 3,549 ambulance calls were answered, 33,488 patients were treated in the dispensary, and 14,100 visits were paid by district nurses.

Cook County Hospital Alumni Association.—At the fortieth annual reunion of this association, recently held, Dr. Nicholas Senn was elected President, and Dr. Frederick A. Besley, Secretary. Speeches were made by Drs. Nils T. Quales, Senn, Ingals, Bacon, and others.

Gift of a Grateful Patient.—A patient injured in an automobile accident near New Brunswick, N. J., while being taken to the Wells Memorial Hospital of that place promised that if he were removed carefully he would present a new ambulance to the institution. Apparently the work of the attachés of the hospital was satisfactory, for shortly afterward a thoroughly modern ambulance was shipped to the institution.

Working Women's Protective Union.—At the annual meeting of the Working Women's Protective Union recently held, Dr. Henry Dwight Chapin was elected president. The work of the society consists in preventing and punishing frauds upon working women.

Harvey Society Lectures.—The fifth lecture in the Harvey Society Course will be given by Dr. S. J. Meltzer of New York, on Saturday evening, December 15, at 8:30 P. M., at the New York Academy of Medicine. Subject: "The Factors of Safety in Animal Structure and Animal Economy." All interested are invited to be present.

The Late Dr. Leroy M. Yale.—At a regular meeting of the Society of the Alumni of City (Charity) Hospital held on October 10, 1906, unanimous action was taken in executive session directing the Secretary to draw up a resolution embodying the deep regret of the society at the death of Leroy M. Yale, A.M., M.D., one of its oldest and most esteemed members.

Dr. Yale was distinguished by the unusually high character of his work, by his contributions to literature, and by his unselfish devotion to his duties. He had by his genial comradeship and by loyalty to his associates endeared himself to all who knew him; therefore be it

Resolved, That we extend to the bereaved family our heartfelt sympathy; and be it further

Resolved, That a copy of these resolutions be sent to the family, and also be published in the medical press. WILLIAM P. HEALY, M.D.,
Secretary City (Charity) Hospital Alumni Society.

Death of Dr. Lapponi.—Dr. Giuseppe Lapponi, personal physician to the Pope, and also to his predecessor, Leo XIII, died on December 7 of cancer of the stomach. Dr. Lapponi was graduated in medicine from the University of Bologna in 1875, and after practising in Capalone, in Tuscany, and Pallenza, near Marcerata, he was in 1888 invited to become body physician to Pope Leo XIII. At the time of the death of Pope Leo, Dr. Antonio Cardarelli impugned the correctness of the diagnosis of pleuropneumonia which was given out by the attending physicians, Drs. Lapponi and Mazzoni. These physicians later on admitted that Cardarelli's allegation that the cause of death was carcinoma was correct, but stated that they had been obliged to take the position they did through the action of the college of cardinals, and produced an affidavit to this effect that they had drawn up early in the illness in order to protect their professional reputations.

Obituary Notes.—Dr. Henry C. Jones of Mt. Vernon, said to be the oldest practising physician in Westchester County, died on December 4, at the age of seventy-three years. Dr. Jones was born in East Hartford, Conn., and received his medical education at the Worcester, Mass., Medical College and the American Institute of Homeopathy. He had practised in Mt. Vernon since 1856.

Dr. ALEXANDER E. MACDONALD of this city died of tuberculosis on December 7, at the age of sixty-one years. He was born in Toronto, Canada, and after studying medicine in the Toronto University was graduated from the New York University Medical School in 1870. He later took a course in the law school of the university and was appointed Professor of Medical Jurisprudence in the university in 1874. After occupying several positions in the hospitals on Blackwell's Island, in 1874 he was appointed resident physician of the insane asylum on Ward's Island, and a year later he was made superintendent. This position he retained until failing health compelled him to relinquish it two years ago. Dr. MacDonald was an ex-president of the American Medico-Psychological Association.

Dr. JOHN HENRY TRENT of Brooklyn died on December 4, of pneumonia, in his sixtieth year. He was born in the Isle of Wight and came to this country in 1867. He was graduated from the Long Island Hospital in 1876, and had practised in Brooklyn ever since.

Dr. P. M. LUSSON of San José, Cal., died on November 26 at the age of sixty-six years. He was a native of Cuba, and after studying medicine at the University of Bordeaux, France, took a post-graduate course at the University of Pennsylvania. He had practised in San José for the past thirty-five years, and was at one time president of the Santa Clara Medical Society.

Dr. SAMUEL R. WATTS of Washington, D. C., died on November 28, after an illness of several months. He was born in Baltimore, Md., in 1846, and was graduated from the medical department of the Howard University in 1872. He was an ex-president of the Medico-Chirurgical Society of Washington.

Dr. W. A. LEE of Richmond, Va., died suddenly on November 30, in his sixty-first year. He had practised in Richmond during the past thirty-five years and had long been Adjunct Professor of Medicine in the Medical College of Virginia.

Dr. CHARLES S. PARKE of Quebec, Canada, died on November 29, at the age of sixty-three years. He was one of the best known physicians of Quebec, of which city he was a native.

Dr. S. D. GUSTINE of Kenner, La., died suddenly on November 24, at the age of thirty years. Dr. Gustine received his medical education at Tulane University, and for some years had been coroner of Jefferson parish.

Dr. FERNAND HENROTIN of Chicago died on December 9, at the age of fifty-nine years. He was born in Brussels, Belgium, and when ten years old was brought to this country by his father, Dr. Jo-

seph F. Henrotin, who settled in Chicago. He entered Rush Medical College, and was graduated with the class of 1869. He began the practice of medicine immediately, and was County Physician during the fire of 1871 and for several years thereafter. He was several times President of the Chicago Medical Society, and was on its Board of Directors when he died. Besides the Polyclinic, Dr. Henrotin was connected with the Alexian Brothers, St. Joseph's, and the German hospitals.

Dr. Wm. J. Luck of Leesburg, Va., died on December 4, at the age of seventy-two years. He was a graduate of the medical department of the University of Virginia and served in the confederate army as surgeon.

Dr. Melancton H. Fisk of Wanwatosa, Wis., died on December 3, at the age of sixty-two years. He was a graduate of the medical school of Ann Arbor University and had practised in Wanwatosa for twenty years.

Dr. George S. Hull of Bristol, Conn., died on December 4, at the age of fifty-nine years. He was born in Burlington, and in 1872 was graduated from the New York Homeopathic Medical College. He had practised in Bristol for over thirty years.

FOURTH HARVEY SOCIETY LECTURE.

The fourth lecture in the present series given under the auspices of the Harvey Society was held at the Academy of Medicine on Saturday evening, December 1. The speaker, Prof. J. G. Adami, took for his subject "The Myelins and Potential Fluid Crystals of the Body."

Professor Adami began by observing that physicians had made but very limited use of the polarizing microscope, although that instrument unquestionably sometimes gave considerable information not obtainable in other ways. He illustrated this by saying that if a section of a fresh adrenal were examined with the ordinary microscope one saw that, in addition to the well-known markings. With the polarizing microscope these globules showed exquisite markings such as were seen in ordinary crystals. The same was true if one examined the freshly expressed juice from the adrenals. These globules, then, were clearly not neutral fat, for neutral fats do not give these markings. If water were added to the fresh juice the markings disappeared; the same was true if the juice were allowed to dry.

Similar globules were obtained when liver or spleen tissue was pounded with alcohol; when the alcohol evaporated the markings seen in the globules disappeared. In 200 pathological conditions it was found that atheroma of the aorta would show similar markings.

What were these globules, and what did they signify? We could call them "myelins," or myelin globules, but that was merely a label and gave no information. Myelin, the speaker pointed out, had been first recognized by Virchow over fifty years ago, and to-day we knew very little more about it. Although these myelins could be obtained from nearly all the tissues of the body, it was curious to see how little attention was paid to them by most writers. Most textbooks omitted all mention of them. They had been observed first by Virchow in smears of fresh brain matter when brought into contact with water. The tissue seemed to send out peculiar fatty processes, often doubly contoured. At the ends of these processes little globules were frequently observed, and these under the polarizing microscope showed the peculiar cross markings referred to. These "myelins" dissolved in hot alcohol. Strong alkalies caused them to shrink. Virchow thought that the myelins were a class of bodies like, for example, the albumins.

The doubly refractive character of these bodies had been observed years ago, and had apparently been forgotten. So long ago as 1857 Mettenheimer had published his observations on myelin, describing particularly their peculiar optical behavior. For the next forty-four years nothing more was heard of this subject. Then, in 1891, Apati, and independently of him Quincke, in 1893, and still others in 1894 and 1898 had published their researches on this class of bodies, and had called attention to their peculiar refractive power. Professor Adami said, however, that it was probable that all of the myelins do not necessarily occur in the form of doubly refractive globules.

Adami's own work began in connection with the researches of Klotz on the processes of calcification, especially of calcification of the walls of the aorta. The speaker described these studies in some detail and ended by showing that Klotz had found that the calcified deposits were preceded by a stage in which there was a kind of "soap" deposit. In this soap the fatty acid moiety was later replaced by the stronger acids, such as phosphoric and sulphuric.

While Adami was visiting Aschoff, the latter suggested that these "soaps" were identical with the myelins already described by Hochheim. Adami then went on to a description of his experimental work with various soaps to discover if these gave the myelin figures. He found that under certain conditions it was quite easy to obtain these crossed figures with ammonium oleate. One placed a drop of oleic acid on a slide and surrounded it with ammonia.

The speaker did not wish to be understood as saying that the globules obtained in the various tissue juices were simple soaps. He believed, however, that study of the latter would throw considerable light on the former. The globules were akin to crystals, but they were not crystals. They were probably not even solid bodies. On treatment with water they became swollen and lost their double refraction.

The significance of these bodies had been indicated by the physicists; a splendid review of the work had been compiled by Schenck of Marburg, who had himself studied the subject for years. The first to appreciate the significance of these bodies had been Löhlein of Carlsruhe, who had published his observations in a voluminous, verbose "Arbeit" of several hundred pages without table of contents, index, or aids of any sort.

Löhlein had found that if cholesterin crystals were heated to 145° a turbid fluid resulted. On examining this with the polarizing microscope it was found to contain a large number of doubly refracting globules, *i.e.* globules showing distinct cross markings. When heated to 178° a clear fluid resulted, and with this change the double refraction was lost, the fluid was isotropous, reacting to light the same as any other fluid. If the process were now reversed, *i.e.* this clear fluid cooled, the doubly refractive globules were again in evidence. Not all of the globules seen in the turbid fluid showed the cross markings. There were always a large number which appeared like ordinary globules. The globules which showed the cross markings would have to be regarded as crystals,

and as they were undoubtedly fluid in character they were spoken of as "fluid crystals." Curiously the globules without the cross markings and the fluid crystals were both the same substance. The cloudy fluid was not an emulsion as some had contended.

Of the substances which exhibited this peculiar behavior oleates and cholesterin compounds were present in the body. There was considerable evidence to show that the myelin compounds in the organism were of an oleate nature. Derivatives of protagon, such as cholin, when brought into contact with oleic acid made the myelin figures easily. Protagon itself did not give the figures. Benecke had been the first to suggest that the myelin globules in the body were of the nature of cholesterin oleate. Adami said that both he and Aschoff shared this opinion.

Cholesterin oleate was, perhaps, also the source of cholesterin gallstones, for Aschoff had shown that myelin globules could be demonstrated in the mucous membrane of the gall-bladder. In the animal body both cholin and cholesterin were two large groups of bodies which could give rise to myelin compounds.

Adami then discussed the autolytic formation of myelin globules. This seemed to go hand in hand with changes in the nuclei. It had been shown by Dietrich and Hegel that in liver autolysis the lecithin decreased, while the fatty acids as well as the cholesterin, etc., increased. With this change there

I.—Intracellular Myelin Globules.

Summarizing the work, the speaker said that in these myelins we seemed to have remarkable substances intermediate between fluids and crystals, and possessing some of the properties of both classes of bodies. The studies indicated that there was a combination of fatty compounds with proteid, and this might give a valuable insight into fatty degeneration. At present it appeared that a "myelinic degeneration" preceded "fatty degeneration."

Myelin globules had been found in the following conditions:

I.—Intracellular Myelin Globules.

(*a*) Physiological or associated with normal regressive change.

Cells of adrenal cortex.
Granular cells of corpora lutea.
Cells of thymus.
Mucous membrane of gall-bladder.

(*b*) Pathological.

Aorta.—Fatty endothelial patches.
Atheromatous areas.
Lungs.—Alveolar epithelium of newborn.
Bronchial endothelium.
Diseased tissue.
Kidneys.—Fatty degeneration, etc.
Lens.—Cataract.
Tumors.—Many carcinomata and sarcomata.

(*c*) Autolytic.

Lung,
Kidney,
Muscle,
Morning sputum.

II.—Diffused Myelin (Impure Lecithin?).

Myelin gained from most of the tissues; from blood, pus, egg yolk, etc., by digestion with alcohol. (Virchow.)

III.—Myelin in Secretions.

Bile (alcoholic extract).
Small intestine contents.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

FITZPATRICK LECTURES—EXHIBITION OF CASES—SUBLUXATION OF ATLAS—DEFORMITY OF CERVICAL SPINE—INFANTILE MORTALITY—LEADLESS GLAZING—OBITUARY.

London, November 24, 1906.

The Fitzpatrick Lectures at the Royal College of Physicians were delivered by Dr. Norman Moore, who took for subject the history of the study of clinical medicine in the British Islands. He attributes the establishment of this study to Sir Theodore Turquet de Mayerne, Glisson, and Sydenham, though there are indications of such observation in Cains, Gilbert, Harvey, and others who, however, are honored chiefly for their works in other branches. They no doubt made many observations of the kind, and probably committed them to writing, but if so their notes have been lost. This is especially the case as to Harvey. Taking then the writings which show strictly minute clinical observations, Dr. Moore instanced Mayerne as the earliest. He had achieved a high position in Paris, and become physician to the King of France before he came to London, and was appointed physician to King James I. in 1611. He has left a full description of the fatal illness of Cecil, the first minister, from which Dr. Moore concludes it was probably a new growth of the cecum. Another description is that of the fatal illness of Henry, Prince of Wales, 1612. From this Dr. Moore found it easy to establish that the disease was enteric fever, which further was epidemic at the time. Like Sydenham, Mayerne gave himself up almost entirely to bedside observations, and both were most occupied with the problems of prognosis and treatment. Glisson, although equally assiduous at the bedside, was also a morbid anatomist, and his mind turned naturally towards the discovery of pathological laws and to questions of etiology. He was a discoverer in anatomy, and described the capsule of the liver. In physiology he first perceived the irritability of tissues. In clinical medicine he completely described a disease not previously known. His *Tractatus de Rachitide* appeared in 1650, and is an example of clinical observation as well as of pathological anatomy. Virchow in the Croonian lecture for 1893 recognized Glisson as the discoverer of muscular irritability, and Sir M. Foster has shown that he was the first to give exact proof that when a muscle contracts it does not increase in bulk. Glisson is perpetually commemorated as an anatomist, but Dr. Moore said whoever studies the *Tractatus* will be convinced that he also deserves recollection as one of the first followers of thorough clinical study in England. As Mayerne may be said to have established this study here and Glisson to have set the example of combining with it the study of the anatomical appearances of disease, so Sydenham may be regarded as the first who attempted to arrive at general laws about the prevalence, course, and treatment of disease from clinical observation. His originality is one cause of the great repute of his writings; and it is due not only to his having thought differently, but to his having seen more than his predecessors. His description of the severe neuralgia which sometimes is the last symptom of a malarial fever, and his determination of the fact that it really belongs to the disease and must be treated in the same way, was instanced by the lecturer as a remarkable example of his close observation. Sydenham hardly considered morbid anatomy, but endeavored to determine the species and ascertain the course of disease by clinical observation only, which is the method of the Hippocratic writings, and thus, though often regarded as the originator of modern medicine, his works might be considered the culmination of the effects of the Renaissance. The three clinical observers were compared. Mayerne, though a less man than the other two, was a noble figure of vast attainments, lifelong activity, and great influence to make men clinical observers; he seems most in personal relation to his patient, thoroughly investigating his mind and body. Glisson was most considerate of the interpretation of well-observed symptoms given by morbid anatomy. Sydenham had always before him the endeavor to establish general laws in relation to disease, and hoped to do so by a precision of description such as that of botanists in describing plants. It was to these three seventeenth century physicians that the lecturer chiefly ascribed the establishment of the clinical study of medicine in England.

On Monday the Medical Society had an exhibition of cases, some of them of exceptional interest. Mr. Gordon Watson showed one of ileosigmoidostomy after excision of carcinoma of the sigmoid flexure, the colotomy wound being still open, in a man of thirty-three. The question of

dealing with the wound was considered. Mr. Wallace suggested division of the large bowel below the wound and anastomosing it with the part above. This suggestion was endorsed by Mr. Barker. The president, Mr. Ballance, said that portions of bowel put out of use became atrophied, and could not be identified. He took a more hopeful view of the prognosis of this case than the other speakers seemed to do.

Two cases of symmetrical myeloid sarcoma, in a boy of fourteen and his sister a year or two younger, were shown by Mr. Sargent. The boy was admitted to St. Thomas's Hospital in August, 1904, with hard swellings on each side in the neighborhood of the bicuspid teeth, but no enlarged glands. The left tumor was removed; it was not encapsulated. It was a giant-celled sarcoma, with much fibrous tissue. In the girl's case some glands were enlarged.

Mr. Barker showed a case of lymphangiectasis of the left thigh in a man of twenty-two. It had existed for six or seven years, and after food the contents of the swollen lymphatics looked like chyle, suggesting a connection with the lacteals. When the swelling became unbearable the patient would prick it and let out the fluid.

Dr. P. Weber had a case of multiple fibrous nodules about each olecranon, with a rheumatoid condition of one foot, in a woman of thirty-seven. The nodules were not tender, but of tough consistence, and near the bursæ. There was also a small nodule on one finger. Patient had rheumatism two years ago, and since then had not been free from symptoms. The nodules came one year ago. Dr. Weber remarked that there was no hard-and-fast line between rheumatoid arthritis and subacute or chronic rheumatism, and even some conditions attributed to gout.

Dr. J. F. H. Broadbent showed a case which he looked upon as early paralysis agitans, in a woman of fifty-four. Doubts were expressed as to this diagnosis. The patient had felt for about a year increasing difficulty in writing, sewing, and any fine movements of the right hand, a sort of stiffness or weakness, and she said her right leg was weaker than the left. The fingers of the right hand were held in the interosseal position. There was no tremor anywhere, no marked loss of emotional expression, and no alteration in her voice.

Dr. Young showed a boy of 3½ years who had been in hospital at Malta several months previously for acute enteritis, followed by pyrexia, and wasting of muscles of both legs, and to a less degree of the arms. There was some recovery, but the legs were cold and blue. Reflexes lost and the boy could not walk alone. No particular group of muscles seem to have been specially affected. Recovery is gradually taking place.

At the Clinical Society Mr. E. M. Corner read a paper on rotatory subluxation of the atlas, dealing specially with those cases in which, as the result of a violent, sudden twist, the head became fixed in a rotated position, usually the result, he thought, of the locking together of the forwardly displaced side of the atlas on the axis by muscular action. The position and fixation of the atlas could be detected by the position of the transverse processes and by the loss of certain movements. He quoted cases and showed diagrams. He also showed skiagrams from a case he showed at the society in October, 1905, and of which I gave you note at that time. The chief use of a skiagram in such cases would be to show the absence of further injuries, such as fracture of the arch of the atlas or of the odontoid. If these could be excluded an anesthetic should be cautiously given. When muscular relaxation was produced the head would probably roll back into its right position, and on recovering from the anesthetic the head movements would be restored. In reply to a question Mr. Corner said this subluxation could occur without rupture of the ligaments, as these are very lax in the atloaxoid joint.

Mr. Jackson Clarke read notes of a case of congenital deformity of the cervical spine in a boy of four, whose head was fixed from birth. The chin was close to the sternum, and there was no movement of extension, flexion, or rotation in the cervical spine, the appearance resembling some anencephalic cases, but the boy's mind was normal. Operation followed by massage gave the boy a short neck with all natural movements. Skiagrams showed extensive abnormalities in the form of the bones in the cervical and upper dorsal spine, and a cervical rib on each side. Mr. Clarke did not know of a similar case operated on, but he had seen the deformity in adults.

The president, Mr. Clutton, congratulated the operator on his success, and observed that there might be in such cases an anterior spina bifida or spinal deficiency.

Yesterday the Prime Minister received a deputation to urge the necessity of legislation in regard to infant mortality. He agreed that the evil was appalling, and that the matter was one of the supreme tests of civilization. He even hoped that what the government did they would not be slow about. But he weakened this by a warning that it would not do to go ahead of public opinion. Clearly he is ready to follow, but, as usual, not to lead.

Mr. J. Burns, as President of the Local Board, was with the premier, and expressed an agreement with the recommendations of the recent conference on the subject over which he presided. He has a bill drafted on milk depots which he hopes will help local authorities. He could promise support by his department, but one chief factor was spending on beer what should be spent on food for the women and children. He said he would be false to his position if he did not warn working men and women that if they wanted healthy children, the less they spent on drink, betting, and gambling, the more they could secure food, and also rest and leisure, so needful to the expectant mother and nursing woman.

An exhibition of leadless glazed china and earthenware is now being held. It was opened on Wednesday, and addresses were delivered on the improvement of the matter. Much was said about the history of changes that had occurred in the manufactures, the influence of accidents and fashion, as well as on the artistic merits of the productions. It was at first said the leadless glazed articles were less durable, but that being disproved, the question of cost is now being raised. That, as was pointed out by one speaker, is only a question of creating a market. Lead poisoning and the injury to health of the workers are the most important points. As to poisoning, the cooperation of manufacturers and government has reduced the number of cases, but these represent only one-seventh of the cases of illness caused by this dangerous employment. Here there is the certainty that, if we could eliminate the use of lead glazing in this country, free trade would flood us with foreign-made, lead-glazed articles.

Dr. Rob Grieve, C.M.G., late Surgeon-General of British Guiana, died at the age of sixty-seven. He was M.D. Ed. and L.R.C.S, 1861, and entered the navy as assistant surgeon. In 1870 he was appointed Medical Superintendent of the Asylum Hospital, Hampstead, afterwards at Berbice Lunatic Asylum. From 1885 to 1894 he was in British Guiana, and for services there received the C.M.G. on his retirement.

Dep. Surgeon-General R. Webb, who died in October, entered the army in 1854, served in the Crimea, the Indian Mutiny, and the Abyssinian War, and was awarded medals and clasps.

Dr. G. I. Schorstein, M.D., Oxm., F.R.C.P., died on the 16th inst., aged forty-three. He was appointed Assistant Physician to the London Hospital in 1894, and became full physician last year. He had the chair of Medical Pathology at the college. He was also physician to the Hospital for Consumption. Though a man of high attainments and literary taste, he had not begun to contribute much to the societies or journals, but devoted his energies to hospital work and teaching. It was known to his friends that he suffered from diabetes, so that his early death was not altogether unexpected.

OUR PARIS LETTER.

(From Our Special Correspondent.)

SURGERY OF THE VEINS—OPERATIONS ON THE THORAX—PLEOCHROISM—HEMONEPHROSIS—PROSTATECTOMY—DIRECT VISION CYSTOSCOPY—RENAL TUBERCULOSIS—THE CONGRESS OF ALIMENTARY HYGIENE.

PARIS, November 15, 1906.

THE XIX Congress of the French Surgical Society was held at Paris during the first week of October under the presidency of Prof. Monprofit of Angers.

The first question discussed was the surgery of the large veins. A very detailed paper on this subject was presented by M. F. Lejars of Paris, who reviewed the progress made in this domain during the past ten years. He pointed out that the repair of injured veins by suture was one of the most important advances in vascular surgery of recent years, as in this way the wall of the vessel was restored and the flow of blood was not checked. The success achieved in the operation of lateral suture had led to the method of circular suture, to the end-to-end anastomosis after resection of a portion of the vein, and finally to arteriovenous anastomosis. The speaker reviewed the treatment of various types of injury to the large vessels and described the technique of suture; he then discussed the treatment of arteriovenous aneurysm and the treatment of gangrene of the extremities by means of arteriovenous anastomosis. He also touched on the operative treatment of infectious thrombophlebitis in the large vessels, as in the sinusitis of otitic orgin, and in the resection of the pelvic veins in puerperal sepsis.

The second question taken up concerned the methods of opening the thorax for operative purposes and was dis-

cussed by MM. Charles Willems of Ghent and E. Loison of Paris. The former said that intrathoracic surgery involved two principal dangers, that is, pneumothorax and infection. Too much attention had been paid to the former and too little to the latter. While it was true that the simultaneous opening of both pleural cavities was almost inevitably fatal, the danger of unilateral pneumothorax appeared to have been exaggerated. The gravity of this condition seemed to depend, first, on the size of the pleural opening, for when this had a smaller diameter than the glottis the lung did not contract entirely since during inspiration the air could not enter sufficiently rapidly to do away with the pleural vacuum. Second, on the rapidity with which the air rushed into the chest, for pneumothorax produced suddenly through a large incision often gave rise to serious symptoms whereas the gradual entrance of air usually did not occasion alarming manifestations. Third, the length of time during which the pleura remained open, for the danger increased as this period was lengthened. Fourth, on the side which was involved, for pneumothorax of the right side was more serious than of the left, probably because the vena cava and the right auricle whose walls were thin were less resistant to the atmospheric pressure than the left ventricle. Fifth, on the presence or absence of adhesions. Sixth, on individual peculiarities of the patient, such as the condition of the lungs, the state of the general health, the loss of blood, the state of the heart, etc. The second danger attending intrapleural manipulations was infection, which was more likely to occur in these cases than in operations on any other part of the body, and which was more often the cause of death than was the pneumothorax. The speaker discussed the reasons for this susceptibility of the pleura, and said that it should be combated by rigorous asepsis, by restricting as much as possible the duration of the operation, and by the use of gauze packing suitably placed. At the close of the operation the pleural cavity should, if possible, be closed hermetically, or if this could not be done it should be either drained in its entirety or an apparatus for securing drainage by aspiration should be applied by which means the exit of fluid was favored, but the entrance of air was prevented. As for the pneumothorax, the only method of avoiding this was to make the pleural incision only through sufficiently dense and extensive adhesions. As it was impossible to be sure beforehand of their presence or to produce them artificially, it was usually better to substitute for them a circle of pleuropleural sutures in the center of which the opening was made.

Ectopy of the testicle and its complications was the third topic discussed. M. Villard of Lyons, in his address on this subject, stated that the etiology of this condition was still in an unsatisfactory state in spite of the numerous theories that had already been presented. He reviewed the theories of various authors and finally suggested that it might be concerned with the general question of degeneracy and heredity in view of the frequency with which this anomaly was observed in degenerates. Even though in some cases the displaced testicle might attain almost normal dimensions, it always revealed profound changes in the epithelial elements and in the seminiferous tubules. This was in accordance with the clinical facts in cases of bilateral cryptorchidism, that is to say, potency and the sexual appetite were preserved, but the semen had no fecundating power. Cryptorchids were often sterile, but not impotent. It thus appeared that true cryptorchidism involved a double interference with development, both the migration of the gland and the seminiferous epithelium being modified. The speaker then discussed the various methods of orchidopexy, and said that these included two main stages; first, the drawing down of the testicle, and, secondly, its fixation in its new position. He believed that success was most surely attained by providing for a sufficient displacement of the gland, and this was the most certain means of guarding against its reascent. Elongation of the cord to a sufficient degree and accurate anatomical closure of the canal by Bassini's method were also important parts of the operation. Anatomically, the results of orchidopexy were good, since out of 116 operations there were reported 56 in which the result was perfect, 42 in which it was doubtful, and 18 in which there was failure. Functionally, pain was relieved and the virility of the patient was increased, but in the vast majority of cases there was no effect on the function of spermatogenesis. M. Souligoux of Paris, in speaking on the same subject, said that from the pathological standpoint two varieties of cryptorchidism might be recognized. First, ectopy of the testicle due to defective development or malformation of the testicle and its vessels; second, ectopy due to malformation of the enveloping structures, that is, the peritoneal folds, inguinal canal, and scrotum.

The tenth session of the French Association of Urology was held at Paris October 4-6 under the presidency of Prof. Guion. The etiology and treatment of hydronephrosis was discussed by MM. Pierre Duval and R. Gregoire. They stated that a study of the different factors that might give rise to hydronephrosis could be referred to a consideration of congenital malformations. The etiology of acquired hydronephrosis was dominated by these principles of congenital malformation. The other factors usually considered in the etiology of hydronephrosis might be relegated to a secondary place, such as compression of the ureter, traumatic, inflammatory, or neoplastic lesions, the presence of calculi in the pelvis of the kidney or in the ureter, as well as kinking of the ureter over abnormal vessels. The treatment of hydronephrosis should differ according to its varieties. After condemning the simple evacuation of the ureteronephritic sac either by nephrotomy or by repeated catheterization of the ureter the speakers stated that they considered that two methods only should be practised; the one was the radical operation of nephrectomy, the other was conservative, but was variable in its applicability. It consisted either in a plastic resection of the pelvis of the kidney, in anastomosis between the ureter and the pelvis, or in simple nephropexy, which, although of itself of little service, might be a useful supplement to the preceding procedures. Nephrectomy should be done only in exceptional cases, when it was evident that the renal parenchyma had been completely destroyed, otherwise conservative plastic operations were to be preferred.

The indications and technique of prostatectomy were made the subject of an interesting discussion. M. Pauchet of Amiens said that he had performed the operation nineteen times according to Freyer's method, and stated that he considered this easy, rapid, and safe, providing that the postoperative treatment was properly carried out. The results, he said, were marvelous, and he considered that the modifications to the operation proposed by some surgeons introduced needless complications and rendered the prognosis less favorable. The result was to transform an operation that was, to be sure, blind and brutal, but essentially conservative, easy, and efficacious into a procedure that was elegant, but long and severe. For him no changes were desirable in Freyer's operation, which required simply a bistoury and a needle and which should be performed in from three to six minutes. M. Legueu then described the improvements he had made in the operation of suprapubic prostatectomy; the most important features being the control of hemorrhage and the preservation of the prostatic mucous membrane. M. Carlier of Lille also advocated the transvesical operation, and M. Loumeau of Bordeaux expressed himself to the same effect. Several other speakers also spoke in favor of the suprapubic operation in preference to the removal of the gland through the perineum.

The use of the direct vision cystoscope was described by M. Luys of Paris, who emphasized the advantages of the instrument. By this means it was possible to see clearly localized areas and also to subject the entire surface of the vesical mucosa to a searching scrutiny. In catheterizing the ureters it was possible to avoid infection of the healthy ureter, and the operation was feasible even if the bladder were inflamed or bleeding. The method was also of great service in the removal of foreign bodies from the bladder and for intravesical operations. M. Jeambrau of Montpellier reported two cases in which the intravesical segregation of the urine of the two sides by means of the instrument of Luys had not rendered a complete diagnosis possible, and he spoke of the necessity in most cases of also making a cystoscopic examination in order to corroborate and complete the results obtained by the segregation of the urine.

The diagnosis of renal tuberculosis was discussed by M. Desnos, who described a case in which urine obtained through the ureteral catheter contained leucocytes and tubercle bacilli, although the kidney and ureter were on removal found to be free from lesions. Some months later the patient presented signs of a suppurative prostatitis with tubercle bacilli in the urine, and the speaker supposed that some of these organisms had been introduced into the ureter by the ureteral catheter which had carried them on from the neck of the bladder.

The International Congress of Alimentary Hygiene. This congress, which was organized by the Society of Alimentary Hygiene and was inaugurated under the patronage of the President of the Republic, was held at Paris from the 22d to the 27th of October. In the opening address M. Mirman, in the name of the President of the Council, and the entire Government, drew attention to the great interest taken by the French Government in the problems studied by the society and welcomed the official delegates of the foreign countries. He passed in review the advantages of international efforts in this direction, and in

closing expressed the hope that this first congress might be followed by many similar meetings in the future through which much might be accomplished for the good of humanity at large. Senator H. Ricard, the President of the Society, then discussed the scope of the questions which were studied by the society and pointed out the scientific objects to be accomplished. These were, briefly stated, to determine what should be the proper food of man, taking into consideration the various conditions to which he was subjected through differences in age, race, climate, season, occupation, etc., and in what way these foodstuffs might most advantageously be obtained. Prof. Armand Gautier then laid stress on the point that the present congress had even more social bearing than scientific bearing. Political economists and scientists were united in affirming that it was especially necessary to disseminate instruction on how to use the various foodstuffs to the best advantage. Although nothing was more useful than this, few subjects had been so much neglected as the problems involved in this question. The rules that had already been formulated for the care of animals did not exist for the human race. It was now the duty of the States to assist as much as possible in advancing the work of securing and imparting information on this subject, the importance of which had been shown by the recent researches made by scientists on the sources of tuberculous infection in foodstuffs. M. André, the Belgian delegate, in closing the first session, in the name of the foreign delegates, congratulated France on having assumed the initiative in assembling the physiologists, the chemists, and the economists for the purposes of this congress.

THE TREATMENT OF ACUTE SEPTIC PERFORATIVE PERITONITIS, CAUSED BY THE BURSTING OF AN ABSCESS DIRECTLY INTO THE ABDOMINAL CAVITY.

To the Editor of the Medical Record:

Sir:—In an article on "Report of Laparotomies, etc.," by Drs. Marshall and Quick, published in the Medical Record of November 24, the following statements are made: "We operate on every case when the radial pulse can be felt. Early, intermediary, and late operations, as defined by hours, days, are terms that should be relegated to the attic, etc. We have awakened from that condition which makes a god of pulse and temperature." Or, in other words, they care nothing for the condition of the patient and the period of the disease. All they want is the diagnosis and a pulse at the wrist when they cut away. I stated that there were more deaths from appendicitis due to "operate-as-soon-as-the-diagnosis-is-made" plan than were due to the expectant plan of treatment. This was true up to 1903, when the treatment of appendicitis was placed upon a scientific surgical basis. Since that time the death rate in appendicitis has decreased one-half in the State of Iowa (statistics of 1904). Dr. Brownson says: "No case of acute septic peritonitis caused by the direct perforation of the peritoneal cavity (produced by the bursting of an abscess pouring the septic contents directly into the abdominal cavity), will be found with a temperature of 102° and a pulse of 120. Rather will they have a temperature of 105° or 106° and a pulse of 140 or 160, together with a leaky skin, etc." They then proceed to give the history of two cases of injury to the abdomen in which operation was performed, one patient dying, the other recovering, and attempt to show that if Dr. Brownson's theory of temperature of 105° or 106° and a pulse of 150 or 160 are necessary to the diagnosis of acute septic peritonitis from direct perforation of the abdominal cavity, both patients would have been dead instead of one. I will not take up the space to quote these clinical cases in full, for the reader will find them reported on page 811 of the Medical Record of November 24. Any one reading the description can see at a glance that there is no analogy between these cases of external injury to the abdomen, and the internal diseased condition of acute septic perforative peritonitis from rupture of an appendical abscess into the abdomen, which was the subject I was discussing. The absurdity is so plain that it demonstrates itself.

Again they quote: "If Dr. Brownson is not convinced, and still believes that cases of acute septic peritonitis from perforation (by direct rupture of the abscess into the abdominal cavity) are forlorn tasks with which a surgeon should not risk his reputation, let him attack Dr. John B. Murphy, who reports to the American Association of Obstetricians and Gynecologists, thirty-six consecutive cases of general suppurative peritonitis from perforation, with one death." We will not attack Dr. Murphy, but rather will we consult him, for he has already given his opinion in the discussion, and in private conversation at the very meeting, and upon the very paper to which they refer us, as is seen in the following, published by Dr. J. F. Baldwin in the *Journal of the American Medical Association* of November 17: "In cases of general purulent peritonitis the process has been going on as a rule for five or six days, the abdomen is distended, peristalsis has ceased, the hippocratic countenance is marked, the pulse is usually though not invariably rapid, while the temperature may vary from high to subnormal. I have never seen recovery occur in one of these cases, and I never expect to. When, therefore, I saw reports of cases of 'general suppurative peritonitis' in which patients had recovered under redrainage of the pelvis, with the patient in Fowler's position, with or without rectal injections of saline solutions, I felt that I had not been doing my own patients full justice, and accordingly in two or three cases of the character described above I resorted to this treatment, but without the slightest possible benefit.

At the meeting of the American Association of Obstetricians and Gynecologists in Cincinnati, last September, Dr. Murphy read a paper reporting thirty-six cases of "general suppurative peritonitis from perforation, with one death." In the discussion which followed, however, in response to a direct question, and later more fully in private conversation, he stated that he did not mean by this title cases such as those described above, but that he included under this title all cases of peritonitis resulting from perforation, no matter whether the perforation had taken place an hour beforehand or several days. Patients such as those mentioned, he said, were "dead already," and nothing could be done for their relief.

With this understanding, therefore, of what is meant by certain writers when they report cases of "general suppurative peritonitis" terminating in recovery, I think we can all look back over our cases of local peritonitis, though without protecting adhesions, in which we have had prompt recovery following operation and drainage, and in which we have not at any time felt that we had accomplished anything so very wonderful.

If Drs. Marshall and Quick are not yet "rudely awakened from their childlike simplicity, and are not convinced that cases of acute septic perforative peritonitis (from rupture of an abscess directly into the abdominal cavity) are forlorn tasks," let *them* "attack Dr. J. B. Murphy," a surgeon who has always evinced a great solicitude not only for "his own reputation" but for the "science of surgery."

J. J. Brownson, M.D.

Dubuque, Ia.

REMARKABLE FLEXIBILITY OF THE TONGUE.

To the Editor of the Medical Record:

Sir:—I wish to report a case of remarkable tongue power in a female patient of mine. Miss N. came to my office during October last for advice as to a nasopharyngeal catarrh. She mentioned to me that the opening of the Eustachian tube was much larger on the right side than on the left, and when questioned as to the source of her knowledge, said she could feel it with the tip of her tongue. On my expressing doubt as to her power to accomplish this, she at once passed her tongue rapidly behind her soft palate into the pharyngeal vault, and even protruded it into each nasal fossa, so that it could be easily seen through the anterior opening if the alæ nasi were held open and illuminated. Strange to say, she could protrude her tongue but a short distance beyond her lips, and her soft palate was very rigid. She resented the use of a palate retractor very much, claiming that it caused her great pain, even under cocaine, so that I was unable to satisfy myself as to the correctness of her claim of the difference in size of the tubal orifices.

Progress of Medical Science.

New York Medical Journal, December 1, 1906.

A Clinician's Observation of Opsonic Therapy.—C. D. Aaron gives his impressions from personal observation of the work of Wright in London. He briefly reviews the broad scientific principles underlying the plan. Opsonin is defined as an ingredient of the blood serum which aids phagocytosis by its inhibiting action on a given microorganism. The opsonic "index" is the opsonic content of normal healthy blood. The index for any particular pathogenic microbe is determined by mixing with fresh human leucocytes the serum to be tested, and an emulsion of the particular bacterium under investigation. After a short incubation this mixture is spread as in making a blood film, stained appropriately, and then examined with suitable microscopic power. The phagocytic leucocytes will now be revealed containing the bacteria in their substance,

and by counting the contained bacteria in a sufficient number of leucocytes, striking an average, and comparing it with a normal serum, the opsonic index for that particular serum and that particular microbe is obtained. In actual practice the determination of the opsonic index can be satisfactorily executed only by a properly equipped laboratory expert sufficiently experienced in bacteriology and serum pathology, and the same consideration applies to the production of the various vaccines, and further, of course, to such steps as the isolation and identification of a given infecting microorganism and the preparation of a vaccine from it. Aaron finds that among Wright's London colleagues the value of the latter's work is highly appreciated. Three principal classes of cases have thus far been treated, viz., chronic pyogenic infections, malignant neoplasms, and various forms of tuberculosis. Pneumococcus vaccine has been used with good effect in chronic empyema following pneumonia. Colon bacillus vaccine alone, or combined with that of some other organism which may be associated with it in the lesion, has been successfully applied in chronic appendicitis, peritonitis, cholecystitis, cystitis, and pyelonephritis, and especially in the unhealing suppurating conditions where the fistulæ remain after abdominal or pelvic operations for various acute or chronic infections. The author quotes Wright as stating that the complete rest in bed, which gradually reduces the temperature in the large majority of cases of pulmonary tuberculosis, is to be regarded as a therapeutical measure for ending those autoinoculations which follow every overexertion. All consumptives laid out on cots and chairs in our seaside or mountain health resorts, or in open-air sanitariums, demonstrate the arrest of the influx of tuberculous poison into their blood by their great gain, for they soon show an appearance of improved health. Wright says: "If only to the appreciation of this fact there could be added the belief that the cure of bacterial infections depends neither upon storage of fat, nor upon the bronzing of the skin, nor yet upon the breathing of fresh air (sea coast air, country air, pine wood air, mountain air, or warm southern air), but only upon the destruction of the invading bacteria by the antibacterial substances of the blood (with or without the cooperation with the leucocytes), we should, I think, have come close to the truth."

Etiology of Cholelithiasis.—This paper, by J. Funke, is based on a bacteriological study of 102 calculi. After describing his laboratory methods, he gives the results of his investigations, stating that of the above number but 31 gave rise to growths on culture media. All the rest were sterile. Only now and then were bacteria found in spreads, and occasionally, perhaps in three calculi, were bacteria found in the spreads when no growth from the same calculus developed in the bouillon. From the infected tubes the colon bacillus was isolated eleven times in pure culture. The *Bacillus typhosus* was found once in pure culture and never associated. The following organisms were isolated once; occasionally they were in pure culture, occasionally associated: *Bacillus limbatus, Bacillus gasoformans, Bacterium oxygenes, Bacillus Friedlander, Bacillus lactis erythrogenes, Micrococcus tenacatis,* and the *Bacillus subtilis.* The last named organism was found in pure culture in eight of ten stones taken from the same case. The *Sarcina lutea* was found in four calculi always associated with one or more organisms; the *Micrococcus cereus albus* was isolated twice. One calculus yielded a bacillus which could not be identified; it resembled the *Bacillus brookeri* very closely. Soft concretions invariably yield bacteria, which are more common in recent cases than in old ones. Drying causes either death or diminution in the propagating power of the organisms, so all calculi should be examined immediately after removal from the body. The general opinion obtains that cholelithiasis is responsible for suppurative lesions. Catarrhal conditions are perhaps necessary for two reasons: First, in order to secure sufficient mucins and pseudomucins to agglutinate the salts formed during the inflammation, and second, in this condition the epithelial cells undergo a set of changes degenerative in nature, during which cholesterin is elaborated; whereas, if infection be severe, death of the cells is rapid and distinct. Necrotic changes result, rather than degeneration. Infection and impediment to the bile outflow are necessary factors in causing the condition, but infection of the gallbladder may occur without cholelithiasis. The author finds but little to support the view advanced by Cushing that bile has the property of agglutination to cause clumping of the typhoid bacillus.

Tuberculosis of the Kidney in an Infant.—J. L. Morse reports one case, the patient being a male infant with urinary symptoms appearing at about the sixth month. A definite etiology was never determined. At the sixth month the urine became turbid, with an offensive odor, and contained considerable albumin. Sediment was composed entirely of pus. This was supposed to be due to mild cystitis or pyelitis, but examination showed many tubercle bacilli. The child was at this time running a temperature of 103° or 104°. Fresh air treatment was at once begun and the child placed under the best possible hygienic conditions. It gradually began to gain, though it was over a year before the urine became permanently and entirely clear. One year later the child was reported as healthy in every way.

The Use of Arsenic in Pneumonia.—Six hospital and four private cases are reported by T. F. J. Dunn. Of the former all but one, and of the latter all, recovered. The medication employed consisted essentially in the use of large doses of Fowler's solution of arsenic. In some cases nothing else was employed, and it was found that enormous doses of the drug were tolerated in a most surprising manner. Five minims every two or three hours were given in these cases for several days without the slightest evidence, either proximate or remote, of arsenical poisoning. In fact, it would seem that these patients showed the same tolerance of arsenic that malarial patients show of quinine, or that syphilitics do of mercury or iodide. Aside from the absence of untoward symptoms there seemed to be positive results in the control of the toxemic symptoms of pneumonia. In several of the cases there was a decided break in the temperature about forty-eight hours after the beginning of medication. Epitomized histories are given of all the cases treated. The mode of action of the drug in pneumonia is unknown. "Arsenic," says the author, "is classified as a general tonic promoting the appetite and digestion, increasing the cardiac action, the respiratory power, etc. It is antiseptic, and possesses antiperiodic power, second only to quinine." From a consideration of these properties he is encouraged to believe that it can also exert some control over the processes associated with the development of the pneumococcus.

Journal of the American Medical Association, December 8, 1906.

Symptoms of Cancer of the Uterus.—J. G. Clark thinks that there is little danger of a too alarmist attitude in this matter. The old notion that marked irregularities, floodings, and leucorrhea at the menopause are normal in any sense should be done away with. Another fallacy with serious consequences is the hereditary theory, the assumption too common in the past, that symptoms could not mean cancer, because there was none in the family history. The fact that cancer is a disease of middle life also cannot be too strongly emphasized. As he shows by a chart, at least 90 per cent. of the cases occur between the ages of 40 and 50. Another fact on which stress has been laid is the importance of injuries of childbirth as a causative factor. Sampson has shown that in 412 cases only 3 per cent. had not been pregnant. The suggestive signs calling for an exhaustive examination in a woman between 22 years of age and the menopause are given by Clark as follows: "1. Any deviation of the menstrual period in the way of an excess or an intermenstrual discharge, especially in women beyond 30 years of age. The most suspicious of these are: (a) a mere show after slight exertion, defecation, or coitus; (b) increasing length of the period, even if only one day more than has been her established habit. Every woman is a law to herself in this respect. 2. An exacerbation in amount or change in character of the discharge in a woman who may have had a simple leucorrhea for months or years. Of these changes a free aqueous, acrid, or blood-tinged discharge is especially portentous. 3. A leucorrheal discharge in a patient who has never had it before. 4. Every atypical discharge in a woman after the menopause. These individuals are especially liable to cancer, and should, if possible, be even more exhaustively examined. 5. Pelvic pain of more than a few days duration should be an urgent reason for examination, although it is very seldom an early symptom of cancer." Clark insists on the use of the microscope, especially when in doubt as to the diagnosis from the early symptoms. In case of cancer of the fundus of the uterus the microscope becomes the principal diagnostic aid.

Radical Operation in Uterine Cancer.—A. von Rosthorn sees hope in the researches as to the nature of cancer and recognizes future therapeutic possibilities, but admits that our present resource is in surgery, and since cancer is, in its beginnings, a local disease, the importance of early operation is self-evident. We can not, nevertheless, assure ourselves of the absolute restriction of the disorder, even when first recognized, hence the need of thoroughness in operation, and he points out the advantages of the abdominal method in securing this. There are certain limitations even to this, and he goes at length into the discussion of the method by which the cancer extends itself by way of the lymphatics. In the future, he thinks, we must direct our efforts to the selection of cases that give promise of favorable results, for surgery will be of no avail when the disease has extended beyond certain limits. The system should be thoroughly built up before operating. The narcosis should be shortened as much as possible, the danger

of infection during operation must be carefully guarded against, and he goes in some length into the various details of technic which he thinks will be advisable in our future work. Cases of cancer must be examined more carefully as regards their morphological characteristics and their clinical types, and we should investigate further the conditions and phenomena of recurrence. He concludes with the following suggestions: "1. The abdominal operation is the most rational for the treatment of carcinoma of the cervix, since by its employment the most extensive removal of the parametric tissue is made possible. 2. The view that glands are involved only in later stages of the disease must be dismissed, and the fact that we sometimes find participation of the glands in the very early stages of uterine cancer has convinced me of the necessity of removing the glands in all cases, as I have always done. 3. Based on my own experience, I urgently advise it as our duty to operate in cases of recurrence which have not advanced too far for such procedures. On this account alone it is important to reexamine at frequent intervals (every eight weeks) after the primary operation."

Criminal Abortion and Illegitimacy.—Home education and the development of self-control in the young is the remedy for illegitimacy, according to J. H. Carstens. If the mothers would explain the physiological processes of reproduction to their daughters, he says, there would be very little illegitimacy. As regards the crime of abortion, he thinks religious teaching has been very weak, and this failing, we should impress on the minds the great immediate danger and the chronic invalidism that follows in many cases. We should also help the unfortunate unmarried by showing them how legitimately to avoid exposure. There is, however, a deeper-seated reason, and that is, he thinks, the tendency to late marriage, and to the correction of this, as well as to home training, must we look for the cure of the evils of illegitimacy and abortion.

Education in Sexual Hygiene.—H. O. Marcy speaks of the need of the education of the young in matters of sexual hygiene as a factor in the prevention of illegitimacy and criminal abortion, and holds that instruction as to the material advantages of a correct life and the dangers of unchastity can be convincing to a young man of average intelligence, and even more to a young woman, even if they feel that it calls for self denial. Virtuous training alone may suffice, but will be still more effective if thus reinforced. Young married couples should also be instructed as to the dangers as well as the moral evil of abortion. He regrets the modern tendency to delayed marriage, especially in the class best fitted for parentage.

The Protection of the Innocent.—E. L. Keyes, Jr., believes that while the physician can start the movement for the education that is needed by the public in the campaign against sexual vice, and can furnish material and arouse enthusiasm, the really ideal instructor, so far as his experience and observation go, for men is the Y. M. C. A. physical director. He is half medical man, half teacher, and is vitally interested in the problems involved. He has found also that such men are much more practical in their ideas as to how this education is to be handled than are most physicians. They view the subject from a pedagogic rather than a medical standpoint, and are already equipped with a large fund of practical educational experience. To such men, he thinks, we should confide the actual working out of these educational problems among men; and to similar women teachers among women if the mother is not available. There is, however, one side of the subject that physicians alone can attack. We can give full warning to venereal patients of the danger they are to others; no venereal patient should pass out of our doors without a full knowledge of the infectiousness of his disease; this should be a matter of conscience and professional duty with every one of us. If one can do more, so much the better, but if every medical practitioner would do this much, he thinks, more would thereby be accomplished than by any other single effort toward the protecting of the innocent.

Surgical Kidney.—G. F. Lydston publishes a number of clinical histories of cases of surgical diseases of the kidneys. In connection with cases reported of malignant diseases, he remarks that while blood in the urine, in conjunction with a solid tumor of the abdomen located behind the colon, is generally regarded as pathognomonic of renal cancer, exceptions occur in which hemorrhage is wanting, as Roberts has shown. Hematuria also is not constant in the beginnings of renal cancer, as two of Lydston's cases here reported demonstrate. As a rule, however, it occurs in considerable quantity. A case of kidney abscess illustrates the recuperative power of the kidney, which, after the operation, only a mere remnant, resumed its functions. Although it is difficult to lay down rules, Lydston is inclined to deem it safer to perform only nephrotomy unless there are special indications for nephrectomy in a given case. Another case of sarcoma followed an exploratory operation for suspected calculus, which revealed no evidence of neoplasm. This and a similar case in the author's experience are suggestive of a premalignant stage of such growths, and raise the question as to whether a nephrectomy would not sometimes be justifiable in cases in which all the symptoms of calculus are present, but none is revealed by exploratory operation. The possibility of a circulatory disturbance existing and being responsible for the symptoms must of course be considered. Other cases reported are of tuberculosis and of calculus.

The Lancet, November 24, 1906.

Ectopic Gestation Occurring Twice in the Same Patient, in Both Instances the Uterus Being Retroverted.—The case is reported by C. A. P. Rowse. The patient was a II-para, in whom the usual symptoms appeared toward the end of the second month. Abdominal incision showed rupture of the right tube with a pint of blood between the two layers of the broad ligament. This was evacuated by the extraperitoneal method. The ovary and tube were not removed. A similar experience happened nine years later, no intervening pregnancy having occurred. At this time, behind and to the left of the uterus was a large adventitious sac containing the ovum and about a quart of blood. The sac was formed by the posterior wall of the broad ligament in front, the ruptured tube above, and the intestines posteriorly. The clot and ovum were removed along with the tube and ovary on that side. The right tube and ovary were found to be bound down by adhesions and were not removed. The patient made a good recovery.

Amyl Nitrite in Hemoptysis and Other Hemorrhages.—Further experience in the direction suggested by the title has convinced F. Hare of the value of this drug. Several additional cases are reported. Hare has now records of 34 cases of hemoptysis, and in all but one the bleeding ceased immediately upon nitrite of amyl inhalations. The quantity used has been from 3 to 34 minims. He calls special attention to the work of Pic and Petitjean, who have demonstrated experimentally the action of the remedy. Dogs weighing from 15 to 20 kilograms were curarized, part of the chest wall removed, and artificial respiration was performed. Amyl nitrite was then injected into the femoral vein. Within a few seconds white patches commenced to form on the surface of the lung. These steadily extended, then coalesced, so that finally in from two to three minutes all, or nearly all, the lung parenchyma became exsanguine. This extreme effect lasted several minutes, but from seven to ten minutes elapsed before the normal rose color returned. It would seem that the vasomotor influence of the drug, at any rate, upon the pulmonary circulation, is more enduring than has been suspected. The hemostatic power of the vascular change was demonstrated by snipping the anemic lung with scissors, when hardly a drop of blood exuded. Pic and Petitjean consider that the drug acts through an active vasoconstriction of the pulmonary system, not less than through vasodilation of the systemic periphery. They state that synchronously with the paling of the lung there is a rise of pressure in the pulmonary artery. Against this conclusion, however, must be placed the clinical fact that amyl nitrite is equally efficient in many hemorrhages from the systemic vessels. Menorrhagia, apparently from any cause, may, as a rule, be effectually controlled by a single inhalation a day.

Perforated Gastric Ulcer: Operation; Recovery.—Two successful cases are reported by D. Macartney. In Case 1, a healthy man of 41 years was suddenly seized with griping abdominal pain, and was operated on in twelve hours. Perforation of the anterior stomach wall was found midway between the curvatures and about three inches from the pylorus. No stomach contents of a gross character had escaped. At the site was what was at first regarded as a fat globule, which the operator's finger might have dislodged from the supraperitoneal layer or from the omentum, but closer examination showed it to be a pioneer granulation formed on the serous surface as the final step in the ulceration. The treatment and subsequent history are without any special features. Case 2 was that of a man of 29 years with stomach symptoms suggestive of flatulent dyspepsia lasting over a period of several years. He had dieted himself somewhat, avoiding vegetables, but his seizure of abdominal discomfort became more frequent. In the course of a few hours after a sudden seizure of severe epigastric pain and vomiting, he was operated on. On the anterior gastric wall toward the pylorus was found a clean punched-out perforation. The ulcer was excised by an elliptical incision an inch in length and the edges of the wound were closed by three rows of continuous suture, as in gastroenterostomy. There was a track of inflamed area from the vicinity of the ulcer leading backward toward the junction of the liver and the right kidney. The area was visible by the white exudation due to the escape of part of the contents of the stomach. This was carefully

wiped away with gauze sponges and then copiously washed out with salt solution. There appeared then so little contamination that it was deemed right to close the abdominal wound completely, and to do without draining either there or in the flanks. A quantity of the saline solution was purposely left in the peritoneal cavity. The subsequent course was uneventful.

The Reciprocal Relations Between Affections of the Uterus and Its Appendages, and the Rest of the Body.—T. Wilson enumerates the body changes which take place upon the establishment of menstruation, and notes also the mental alterations characteristic of this period. When normal lactation takes place equally remarkable changes occur in the genitalia. Corresponding retrograde changes mark the menopause. The uterus and appendages are brought into intimate relations with the rest of the system through the nervous system and blood and lymph circulation. The close connection between the uterus and nervous system is embodied in the word "hysteria." Other possible neuroses are migraine, epilepsy, and asthma. Removal of a uterine polyp has cured asthma. In exophthalmic goiter, changes in the female genitalia and their functions are frequent. The condition is often ushered in by amenorrhea. Eight cases are summarized by the author: The marked results that follow upon the complete removal of both ovaries have long been well known, but the exact mechanism by which these changes are brought about is still very imperfectly understood. A considerable amount of evidence has been accumulated in favor of the theory that they depend upon the internal secretion of the ovary, and not upon the action of the nervous system. In osteomalacia it has been found that removal of the ovaries results in the arrest of the diseased process. The disease is characterized by a softening of the bones, and in the later stages by a destruction of proteids, not only in the bones, but in the whole organism; there is a decided increase in the amount of calcium, magnesium, and phosphorus, and of the nitrogen excreted in the urine. The removal of the ovaries is followed by a great diminution in the excretion of phosphorus and by the restoration of the normal firmness of the bones. The results that have been obtained from implantation experiments on animals afford another proof that the ovaries exert their influence on the organism by means of their connection with the blood, and not through the nervous system.

British Medical Journal, November 24, 1906.

The Action of the Salicylates in Rheumatism.—R. Stockman notes that in the absence of any certain knowledge regarding the specific microbe of acute rheumatism and its toxins, it is impossible to determine experimentally whether the salicylates act as bactericides or as antitoxins. Their action on known organisms and ferments is one of inhibition of action of both living ferments and enzymes. In the body their action is conceivably exerted in either direction. Their effect in acute rheumatism is definite and certain. With reference to the characteristic shifting of the pain from joint to joint, and the rapid subsidence of the latter from an inflammatory state without permanent damage, the author says that we should not regard this shifting as a metastasis. The fact rather signifies that all the joints are not invaded simultaneously by the morbific agent. The most probable explanation of the rapid subsidence of the swelling and pain is that locally in the joint an antitoxic or antibacterial substance is formed which powerfully antagonizes the poisonous agent, and does it so rapidly that the joints are very seldom injured. The closed cavity of the joint probably favors the accumulation of the antibody until it reaches a highly active degree of concentration. This view is supported by the circumstance that, while the fibrous tissues of the joints, tendons, and aponeuroses are also very often the seat of rheumatic infection, it is well recognized that in these places the inflammation is usually very persistent, and apt to leave behind permanent fibrous thickenings. This, says the author, is owing to the antibody being in much less quantity in the body serum than in the joint effusion. The explanation of the rapid action of sodium salicylate on the pain and swelling of the joints is that it is excreted into the joint-cavity from the blood in comparatively large amount, as can be readily shown by its detection in the fluid withdrawn by means of a hypodermic syringe. On the other hand, colonies of microbes settled deep in the fibrous tissues, or in the valves of the heart, are more or less sheltered from the action of the salicylate, and are probably scarcely reached by it; or, if reached, the solution in the serum is too diluted to exert much action. This is suggested as the explanation why valvular rheumatic affections and those of fibrous tissues generally are not nearly so amenable to the action of salicylates as the joints are. The important practical deduction to be drawn from this is to treat the patient at once and with large doses, so as to kill off the microbes while they are still in the blood stream or joints, and before they have had time to establish themselves in the fibrous tissues. Early treatment with sufficient doses greatly lessens the risk of acquiring valvular disease and chronic fibrositis.

Rheumatic Fever and Amyloid Degeneration.—Four cases with histories and autopsy reports are studied by J. M. Beattie. He notes the general acceptance of the fact that amyloid changes are generally referred to some long acting bacterial infection. Four cases of cardiac disease following rheumatism, and in turn followed by amyloid degeneration, have come under his notice. The organs affected in the various cases were in differing combinations, liver, spleen, kidneys, adrenals, and small intestines. All the patients were young. All presented the usual history of amyloid disease, viz., a toxin being absorbed fairly constantly for a prolonged period, and, so far as could be made out from the history and from the microscopic examination of the organs, the only poison acting here was that of acute rheumatism. There certainly was neither tuberculosis nor syphilis in any of the cases. It is generally admitted that the causal toxin is bacterial in origin, and in one case an organism corresponding with the *Micrococcus rheumaticus* was isolated. Lending support to the view that the amyloid degeneration was caused by the poison of rheumatism was the relation of the infection to the only definite clinical manifestation of the degeneration—the diarrhea. This was recorded in three of the cases (in the fourth there was unfortunately no record, either clinically or post-mortem, of the condition of the intestine), and in all it appeared just a short time before death. Beattie thinks that these cases give considerable support to the theory that acute rheumatism is a bacterial disease.

Congenital Laryngeal Stridor.—A series of cases is reported by D. R. Paterson. The ages of the patients varied from eight months to two years. Examination was made under chloroform by means of the Killian tube-spatula, the parts about the pharynx and larynx being well cocainized. The influence of irregular and convulsive action of the respiratory muscles as a factor was eliminated, for, in all, stridor became more marked the deeper the anesthesia. On the other hand, it varied notably with the position of the patient, being most evident in the dorsal posture, distinctly less on the side, and with the tongue pulled out, while it was very definitely relieved by placing the tube-spatula on the base of the tongue and tilting it forward. On passing the tube-spatula the curving of the epiglottis was noted in varying degree and the approximation of the aryepiglottic folds, but the most striking appearance was the extraordinary excursion of the posterior wall of the larynx. With each inspiration the soft parts on the cricoid, including the arytenoids and the interarytenoid folds, disappeared, so to speak, into the interior of the larynx, being drawn downward and forward, and to such an extent in pronounced cases that the upper border of the cricoid could be seen as a transverse ridge through the stretched mucous membrane. Diagrams show this change in position of the posterior wall. It was this movement which produced the stridor. With the aryepiglottic folds coming into close apposition during inspiration, the passage of air was only possible by the downward and forward displacement of the posterior wall through suction, and it was the vibration of this section of the laryngeal entrance which gave rise to the noisy stridor. This was confirmed when the posterior wall was held back by means of a curved probe and the air passed in easily and without stridor. If a short tracheal tube (child's size) were inserted just within the entrance of the larynx, all noise at once ceased, the glottis appearing quite normal, and showing no sign of spasm or paralysis of the vocal cords. Pushing the tube further, the trachea was found unaffected in all, and there was no encroachment on its lumen, so that the influence of an enlarged thymus must be regarded as accidental, and no part of the classical affection. With expiration the parts resumed their natural upright position, and at the end of that act the larynx had the appearance of the slightly accentuated infantile type. Paterson's conclusions differ from those generally accepted. In his own words, they are as follows: (1) There is no malformation beyond an exaggeration of the natural incurving of the infantile epiglottis which can easily be unrolled by the probe. (2) There is no evidence of abnormal breathing, as has been suggested by other authors. In deep anesthesia the breathing is regular and the stridor very marked. (3) Stridor takes place at the entrance of the larynx by vibration of the soft structures on the posterior wall. The vocal cords take no part in its production.

Preventing Hemorrhage in Operations on the Skull.—On either side of the projected line of incision a long needle carrying a heavy silk ligature is passed between the scalp and the skull. The two ends of the ligature are then tightly tied over a suitably curved strip of metal so as to compress all of the vessels about to be cut through.—KRADEL, *in Zentralblatt für Chirurgie.*

Book Reviews.

THE MEDICAL RECORD VISITING LIST or Physicians' Diary for 1907. New Revised Edition. New York: William Wood & Co.

THIS well-known visiting list is again to hand, and contains, in addition to the usual pages for patients, etc., many valuable items of information. Tables of dosage, duration of pregnancy, antidotes, signs of death, artificial respiration, and hints on the making of wills are to be found in the first thirty pages of the book. At the end of the volume are pages for special memoranda, consulting practice, obstetrical engagements and practice, record of vaccinations and of deaths, addresses of patients and of nurses, and for cash accounts. The book is of convenient size for the pocket and is handsomely bound in flexible morocco.

DIET AND FOOD, Considered in Relation to Strength and Power of Endurance, Training, and Athletics. By ALEXANDER HAIG, M.A., M.D. Oxon., F.R.C.P. Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women. Author of "Uric Acid as a Factor in the Causation of Disease" and of "Uric Acid: an Epitome of the Subject." Sixth Edition, with Seven Illustrations. Philadelphia: P. Blakiston's Son & Co., 1906.

THE text of this book, like that of the previous edition, is arranged in four chapters: Some Points in the Physiology of Albumin and Urea; Physiology and Pathology of Fatigue; Foods Available: their Properties and Relative Importance; Values of Food in Albumin and Urea. Quantities required. Diet of Training and Athletics. The writer lays great stress on the importance, both mental and physical, of the correct understanding of dietary questions. He shows that this science which he discusses controls the building of the brain cells. It lies at the root of all the problems of life. It is now realized that many perversions and deformities which were formerly considered to be deliberate and voluntary belong in the realm of the physician, and are as true diseases as is a crippled joint. The stimulative forms of diet, the author believes, are at fault for many of the baffling mental and physical diseases. He thinks that reform of the ordinary diet is imperative.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. September, 1906. Philadelphia and New York: Lea Brothers & Co., 1906.

THE current number of Progressive Medicine commences with a review of the diseases of the thorax and viscera, including the heart, lungs, and blood-vessels, by Dr. Ewart. Special attention is given to pulmonary tuberculosis; the rôle of the lymphatic system, the early signs of the disease, and the treatment, are all fully discussed. The sections on opsonic immunization and the vaccine treatment of tuberculosis are instructive and interesting. Pleurisy, bronchitis, empyema, pneumothorax, asthma, and emphysema are also carefully treated. In the section on the heart particular attention is drawn to the causal relation of the Stokes-Adams symptom to heart block; the anatomy, physiology, and pathology of the bundle of His or Gaskell's bridge are also dealt with. The progress in dermatology and syphilis is carefully reviewed by Dr. Gottheil; Dr. Norris gives an admirable *résumé* of the year's work and literature in obstetrics; and Dr. Spiller performs the same office for diseases of the nervous system. We can only repeat that Progressive Medicine is not only reliable, but also readable

CLINICAL DIAGNOSIS. A Textbook of Clinical Microscopy and Clinical Chemistry for Medical Students, Laboratory Workers, and Practitioners of Medicine. By CHARLES PHILLIPS EMERSON, A.B., M.D., Resident Physician, the Johns Hopkins Hospital, Associate in Medicine, the Johns Hopkins University. Philadelphia and London: J. B. Lippincott Company, 1906.

THE writers of new books on this subject no longer labor in virgin soil, and their predecessors have accomplished enough to make it no easy matter to improve on what has already been done in this direction by some of them. A volume devoted to laboratory methods of diagnosis appearing to-day must therefore be judged by much more rigid standards than would have been the case a few years ago, when the field was still comparatively unoccupied. The present work is introduced with the explanation that it is intended to cover the ground in a somewhat different way by attacking the subject from the clinical rather than from the laboratory standpoint. This ambition is a most laudable one, and so far as it has been carried out reflects nothing but credit on the book. Many sections, for example that on the sputum, and the discussions of the value of routine blood examinations and the testing of the functional efficiency of the kidneys, are admirable in this respect, while the author's general policy in selecting the methods to be described also deserves commendation; but the reader who has allowed his expectations to be unduly aroused by the preface may possibly end his critical scrutiny with the reflection that, like Mark Twain's classical amphibian, this frog has, after all, not so *very* many points of difference from other frogs. None the less, in most of its important features the book is quite satisfactory; so much so that it is a pity the pains were not taken to avoid a number of minor defects. It seems probable that it was both written and put through the press in some haste, for the reader is constantly being irritated by pecadilloes of orthography and diction that just a little more time on the manuscript and proofs would surely have obviated. These are sometimes merely Hibernicisms, as when, on page 460, it is stated that "on the central glass table cross at right angles twenty-one parallel lines," and on page 324 one is directed to use "boiling water at 95° C.," or when, on page 156, it is said that pepsin is "found absent" —sometimes only amusing, as on page 606, where dum-dum fever is called "dam-dam fever"—but sometimes downright misleading to the student, as in the statement on page 318, that in Töpfer's method (spelled Topfer's) the total hydrochloric acid is equal to the sum of the results of the dimethyl-amido-azobenzol and alizarin titrations, and in the reference on page 404 in regard to the presence of placental cells in the blood of pregnant women which conveys the impression that one has only to seek to find them. On page 492 some of the conditions causing leucocytosis are discussed, but though the heading "Mumps" is there the seeker after information on this subject will be disappointed, for it is followed only by a blank space. If what may appear to be undue prominence has been given to these blemishes it is only because they are of a sort that the reader may reasonably expect an author to avoid; numerous other questions which are more or less matters of individual judgment, such, for example, as the omission of any reference to the spirochetes in syphilis or to Sahli's desmoid reaction, have not been taken up. It is to be hoped that the succeeding editions, of which we trust there will be many, will see the volume purged of its crudities and made in all ways as good as it is in most. It would be unfair not to give particular mention to the illustrations, which are numerous, well selected, and worthy of unqualified praise.

TOXICOLOGY. The Nature, Effects, and Detection of Poisons, with the Diagnosis and Treatment of Poisoning. By CASSIUS M. RILEY, M.D., Professor of Chemistry and Toxicology in the Barnes University, and Dean of Barnes College of Pharmacy; Member of American Medical Association; Member of American Pharmaceutical Association. Third Edition, Revised and Enlarged, with Illustrations. Philadelphia: P. Blakiston's Son & Co., 1906.

IT is only five years since the appearance of the first edition of this book; it seems, therefore, to have justified its existence. The volume constitutes a concise and up-to-date textbook for medical students and practitioners who take no great interest either in legal cases or in elaborate methods of chemical analysis. The work is well arranged and will appeal to the busy physician.

DAS PROBLEM DER SYPHILIS und Kritische Betrachtungen über ihre Behandlung. Von Prof. Dr. O. ROSENBACH in Berlin. Second Edition, Revised and Enlarged. Berlin. August Hirschwald, 1906.

ROSENBACH'S monograph is a protest against the abuse of mercury and the iodides in the treatment of syphilis. The idea is not exactly a new one. It has been taught by several syphilographers of the modern school that overdrugging is useless in syphilis as in all other diseases. The old "safe and sane" doctrine was, that if you have a patient with syphilis, keep him pumped full of mercury, and later full of iodides as well, until he has safely rounded the third annual milestone, and then keep treating him with antisyphilitic drugs at intervals as occasion requires.

The author believes that after the disappearance of the secondary and of the ulcerative tertiaries no further mercurial medication is needed; that such patients are best treated by general measures tending to improve their health, by tonics, by proper care of the skin, etc.

The book is well worth reading, but in his abhorrence of dogma Rosenbach grows so dogmatic himself, on the other side of the question, that one can hardly accept his preachings as the last word on the subject.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 26, 1906.

DR. FLOYD M. CRANDALL IN THE CHAIR.

Report of the California Relief Committee.—The Relief Committee of the New York Academy of Medicine and of the Medical Societies of the Counties of New York and of Richmond submitted the following report of their proceedings: The Committee was organized on April 25, 1906, with the election of Dr. C. L. Dana as Chairman, Dr. J. H. Huddleston as Secretary, and Dr. C. H. Richardson as Treasurer. It held nine meetings and issued appeals to the medical profession in New York, individually and through the various medical societies of the city. It was early aided by a gift of $5,000 from the New York Chamber of Commerce, which was given as part of the medical aid fund raised in New York. As a result of correspondence with the President of the San Francisco County Medical Society and Dr. E. T. Devine (representing the Red Cross Society), it was decided that the funds raised should be placed in the hands of Dr. W. I. Terry, Chairman of the Relief Committee of Physicians of San Francisco. Apart from the gift of the Chamber of Commerce, there was received, through 440 individual subscriptions, $5,661.10, and through fourteen societies, $2,040. The societies contributing were the following: The Women's Medical Association of New York City, the Quiz Medical Society, the Metropolitan Medical Society, the New York Society of Dermatology and Genitourinary Surgery, the Harlem Medical Association, the Medical Society of the County of New York, the New York Academy of Medicine, the German Medical Society of New York City, the Eastern Medical Society of the City of New York, the New York Society of Internal Medicine, the Alumni Association of the New York Hospital, the Alumni Association of St. Luke's Hospital, the Yonkers Practitioners' Society, and the Medical Union Society. The disbursements, which covered printing, postage, express charges and clerical services, amounted to $226.52. The amount from medical sources sent to San Francisco was $7,474.58. Drs. C. L. Dana, J. H. Huddleston, and R. H. Sayre signed for the New York Academy of Medicine; Drs. F. M. Crandall, J. V. D. Young, and C. H. Richardson signed for the Medical Society of the County of New York; Drs. C. E. Pearson and G. P. Jessup signed for the Medical Society of the County of Richmond. The report was received, ordered placed on file, and the Committee discharged with thanks.

The History and Principles of the Method of Motor Reeducation in Tabetic Ataxia.—Dr. H. S. FRENKEL of Heiden, Switzerland, read this paper. He said that sixteen years ago when he demonstrated in three cases the principles and methods in the care of ataxic patients much astonishment and mistrust were displayed, but had since disappeared. He recalled two patients, one of whom was a woman whom he had followed for ten years, during which time the condition had remained excellent. He did not wish his hearers to believe the cases reported were accidents; they were all cases of ataxia in the severe stage, and they were made to walk, but only when free from certain complications. After dwelling upon the functions of the upper and lower extremities, showing wherein they differed, he said that ataxia of the upper extremities presented a different clinical picture from that of the lower, that there were different laws of evolution and, consequently, the treatment of the upper extremities required methods entirely different from the treatment of the lower. He then considered the fundamental principles of the method. The principle of the method used was more readily understood when one remembered that the ataxia in tabes dorsalis held an isolated position among the organic motor disturbances; certain tracts of the spinal cord were involved, but not those that conducted motor impulses, only those containing centripetal fibers, *i e* those of sensibility. The two points that had not been clearly called out in the discussion of this subject were (1) in tabetic ataxia the lesion was always contained in the posterior tracts, and nowhere else; and (2) no observation or experiments could be found in the literature which might lead one to think that there were other than centripetal fibers in the posterior tracts. Lesions of the posterior tract caused ataxia. Dr. Frenkel did not agree with Dr. Leyden's statement that cutaneous sensibility had much influence upon motions, and he had been given the opportunity here in New York to demonstrate cases to physicians showing that, in spite of marked ataxia, cutaneous sensibility was but little disturbed. The degree of ataxia depended upon the sensations caused by the muscular sense itself during contraction. The object of the method was then considered. He again emphasized the fact that when a healthy person learned a new muscular coordination, his sensibilities did not show any improvement so far as could be demonstrated objectively. In skating, billiard playing, etc., one acquired the faculty of contracting proper muscles in a proper way, thus gradually eliminating the awkwardness which in the beginning interfered with the proper movements. This, too, depended upon the integrity of the function of the entire motor system from the cerebral centers to the muscular fibers. In tabes this system was intact. In short one could compensate this impairment of sensibility by education, for the reason that the motor system was intact. In tabes one was not dealing with anesthesia but with diminished sensibility. Disturbances of coordination could be eliminated by proper exercises. These patients were taught certain movements; the speaker intended to teach them just as masters taught dancing and riding, etc., by a simplified instruction as to different movements by splitting up different movements into their elements. They must know not only in general but in particular the various phases of those extremely complicated processes in walking and standing. He then explained why the act of standing was so complicated. He wished it to be understood that when one started to walk it was not by reason of the legs but by reason of the trunk or upper part of the body, changing the center of gravity, etc. Tabetic patients often could stand perfectly well on both feet but they were absolutely unable to walk. Without an exact knowledge of the upper part of the body or trunk, no treatment can be applied. The various methods of treatment applied to patients in the sitting posture or by supports were without value in teaching them to walk. He called attention to certain dangers which might arise from the unscientific application of the method; there was great danger in misapplication of the method. The reeducation method should not be confounded with any kind of gymnastics. In applying the method attention should be paid to the subjective symptoms. With regard to results, he said that even in advanced cases, the ataxia could be cured completely, but not the tabes. Those cases gave the best results when the most important symptom was the loss of coordination. The poorest results occurred when there were great impairment of the general health, constant pains with trophic changes, frequently occurring gastric and intestinal crises, etc. He made a public appeal in behalf of tabetics so far as public care was concerned. They were in a peculiar position as compared with other chronic nervous invalids. A protracted course of locomotor ataxia left them in an unchanged condition for from ten to twenty years. The people who had been successfully treated remained throughout the rest of their lives absolutely free from ataxia and many were able to work. Some were unable to work; some were afraid to go about in twilight, others feared slipping while walking, etc. The treatment he advised should be given in institutions, be-

cause it required a great deal of time every day. This educational treatment when well conducted would counteract pauperism to a very great extent. Many could be restored to social independence.

Dr. Charles L. Dana said that locomotor ataxia was a disease which developed in several different ways. There was a small group of cases in which the patient lived ten, twenty, or thirty years without any manifestations except those of continued attacks, and these were cases in which the method of reeducation was not necessary. There was another group of cases characterized by progressiveness, with changes in the optic nerve, with little ataxia or other tabetic symptoms. This group also was a small one and did not require any reeducation. There was a third group in which there was a hypertonic condition of the muscles; they seemed to be too long and too lax. They presented examples of arthropathies. Here, too, reeducation methods did not apply. There was a small group of cases in which there was an involvement of the motor system, atrophic changes occurring in the lower limbs, the muscles becoming weak, etc., and these were the hopeless cases from any point of view. In the majority of the cases of tabes dorsalis the ataxic element was the predominant one; therefore, the method of reeducation applied to the large proportion of ataxic patients. He thought Dr. Frenkel's theory regarding the method of treatment was a sound one and he said he had used it for a good many years and always obtained some results, but not the same success that Dr. Frenkel got. This method was a distinct therapeutic measure in organic disease and a debt of gratitude was due Dr. Frenkel for pointing out the great evil done by the indiscriminate and unscientific application of the measure. Dr. Dana said that even now there was a movement on foot for the public care of ataxic patients.

Dr. Edward D. Fisher said that if anything could be done on scientific lines for this hopeless class of patients it was of vast importance and the method Dr. Frenkel employed appealed to every one. Of course it was more difficult in the case of tabetic than in an ordinary individual to teach him any special set of movements. The principal thing to note was the lack of muscular sense, the patient no longer being able to know whether the flexor or extensor muscles were used: this gave a sense of uncertainty in walking. There was no motor disturbance in the sense of speaking of motor disturbance as a paralytic affection; there was no true paralysis in locomotor ataxia, although there was some loss of tone in the muscles. The wasting of muscles was not a part of locomotor ataxia.

Dr. B. Sachs said it was a matter for congratulation, not only to listen to Dr. Frenkel's exposition of his views. but to note the manner in which he had studied the subject. Such discoveries did not come to the majority of the people unless they were willing to do lots of hard work. Dr. Frenkel's reasoning and studies had been recognized by all of them, and also what he had done not only in educating these tabetics but also in educating the neurologists and giving them a proper conception of the disease. The results of the application of his treatment showed that his views were correct. Seven or eight years had passed since Dr. Sachs had endeavored to carry out the movements. Dr. Frenkel had not shown the movements he employed, not really considering that a very important point; every one who applied this treatment must develop his own set of movements and exercises. He believed that there were a certain number of cases of tabes in which the cutaneous sensibility was distinctly disturbed; in these cases greater difficulty was encountered in endeavoring to teach them to walk.

Dr. Smith Ely Jelliffe said that ten years ago a physician suffered from a severe case of ataxia; he had been a sufferer for years and had made up his mind that the best thing for him was to go to bed. After hearing of this method of treatment and reading of the results obtained from it, he became very enthusiastic and took up the method hopefully and successfully. At present he was able to be about and walked well. Initial experiences with the treatment did not turn out so well as the later ones. Dr. Jelliffe believed it was necessary to distinguish a number of components, each of which had a decided relationship in the prognosis and treatment by this method. To him it seemed as though there were five, as follows: Anesthesia or diminished sensibility of the skin, of joints, and of muscular contractility; loss of reflexes and hypertonicity; disassociation of motor associations; and psychical influences. In each of these there was a certain varying proportion of these components which determined in large degree the capacity for the individual to be improved by this method. There were two types of cases in which there was a bad prognosis, those in which there was a marked degree of muscular insensibility and those in which there was a marked degree of hypertonicity. In both of these classes his own experience had been very limited.

Dr. George W. Jacoby said that his visit to Dr. Frenkel had made him a firm adherent, not only to the principles of the method, but to Dr. Frenkel himself. If any one knew the close attention paid by him to the respirations, the pulse, the heart, etc., they would bear him out in the statement that the method was one which everyone could not take up. One could teach only what one had learned, and every one could not learn this method in a few weeks or months. It should be remembered that there was no tabetic who did not have some amount of sensibility left, and this amount could be educated to a degree that another person with normal sensations in the integument and joints could not attain. With regard to results he said that already in New York City they were beginning to see results. Dr. Frenkel was holding clinics all over, and he claimed to be able to cure ataxia in a great many cases of tabes, and to relieve the ataxia in nearly all cases if sufficient time was given. Dr. Frenkel had taken locomotor ataxia from the category of progressive diseases. The method of treatment was of necessity an institutional one.

Address of the Retiring President.—Dr. Floyd M. Crandall made this address. He congratulated the society upon the manner in which differences had been forgotten during the past year and thought that they had really formed a reunited society in fact as well as in form. The year had been notable, not only on account of the reunion of the profession in New York, but because the most important medical law ever enacted in this State had been enacted on April 4, 1906, and also because this had been the centennial year. A third fact also combined with the two former to make the year memorable. The agreement which brought about the amalgamation also instituted a new system of organization and changed the relations between the State and county societies. In the performance of official duty during this first year of amalgamation it was clearly the duty of the executive body to carry out the provisions of the contract which had been agreed to under the new organization. Previously the society had always been pinched for means and clerical assistance, but modern business methods had now been introduced and all papers and documents were properly classified and filed and made available at any time for reference. The work of the Secretary and Treasurer was voluntary and virtually gratuitous, consequently a competent stenographer and typewriter had been employed. He referred to Dr. Richardson's great labors in connection with the California Relief Committee. Over $30,000 of trust funds had passed through his hands, and over 5,000 accounts, and all this had been accomplished almost without an error. The publication of the Medical Directory had been suspended and the accounts closed, the State Society being able to perform this work more satisfactorily. He spoke of the extent of the work done in the counsel's office. During

the summer the officer detailed by the Police Department to the work of the County Society investigated over 400 complaints and a large number of cases were made ready for prosecution. The Health Protective League, which had just been formed, was in no sense a rival of this society. There would still be left more work along this line than the society would be able to perform. The fines imposed during the past year amounted to $3,785, and the total expenditures for legal work were $4,135. The Milk Commission had enlarged its work and made it much more effective. In legislative matters the society had taken the same active part that it was accustomed to take, and had fought the optometry and osteopathic bills with great energy. Hereafter there would be a standing committee on legislation. There had been a misunderstanding in regard to the membership list which was due to the fact that members had not been dropped for nonpayment of dues, and deaths and removals had not been carefully kept account of. The books of the Treasurer showed that in 1905 1,476 members paid their dues. It was with these figures that the membership of 1906 should be compared. The records to-day showed over 5,000 names and formed a history of the membership of the society approximately correct as far back as 1860, and as correct as it would ever be possible to make it back to 1840. The active list was correct, and showed a membership of 1,839 on December 9, 1905. During the year twenty-four had died and twenty-six had resigned on account of removal. At present there were 2,308 on the membership list. Formerly a solicitor had been employed to obtain new members, but this was not considered wise policy and the practice had been discontinued. Financially, the year had been the most successful one for a generation. The total income aggregated $21,908.56, and there was a balance of $3,094.01 in the treasury. The available income of the society was derived from membership dues alone, and the most encouraging fact in the year's work was the payment of arrears of dues to the amount of $950. Summarizing the effects of amalgamation upon the Medical Society of New York County, he found the receipts from membership dues were $2,198 greater than the average receipts for the five years preceding it, and $1,803 greater than for the year immediately preceding. The keynote of the new constitution was the Comitia Minora, a body of twelve men, to whom all officers, employées, and agents of the society were amenable. The past year had been a laborious one for those entrusted with the administration, but "nothing succeeded like success, and nothing made hard work lighter than prosperity." Harmony and good feeling had made the work a pleasure. He closed by thanking the Comitia Minora for their loyal support and their tireless devotion to the interests of the society.

Resolution Regarding the President-Elect.—Dr. Cornelius G. Coakley offered the following resolution, which was unanimously carried: The Medical Society of the County of New York having been informed of the prolonged and serious illness of the President-elect, Dr. Walter Lester Carr, extends its hearty sympathy, and hopes for a speedy and uneventful recovery.

Address of the First Vice-President.—Dr. H. Seymour Houghton said that the close association of Dr. Carr with the members of the Comitia Minora in all the proceedings of its various meetings during the past year enabled them to say that he was in utmost sympathy with the general plan, and fully alive to the grave duties and responsibilities which had arisen from the new order of things, and from the changed relation upon which the society now entered. This change was indeed one upon which they could not but congratulate themselves, not only because it was the final chapter in the medical history of this city, of a period when honest but such bitter differences of opinion so generally prevailed, but because it had put into action the general and praiseworthy desire that the members of their faith in this city should act as a unit, and by this unification come into normal and natural relation, both with the State and the national body. To their retiring President had come the honor and much of the labor connected with this transitional period. To their incoming President would fall the task of interpretation of this new and revised edition of the society's work. It was for the execution of the will of the society that the Comitia Minora existed, and to the purpose of which it would be devoted with redoubled interest during the ensuing year.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 20, 1906.

Dr. Warren Coleman in the Chair.

The Pneumococcus and Its Infections.—Dr. Pappenheimer presented some general considerations on the pneumococcus and its infections. He discussed first, the question of the identification of the pneumococcus and its differentiation from closely allied organisms. Of the five main criteria, namely, the presence and structure of the capsule, the specific fermentation of inulin, the character of the growth on blood-agar, the pathogenicity for mice and rabbits, and the agglutination reactions, none were always to be relied upon. It was well known that there was a large group of organisms intermediate between the typical pneumococcus and the typical streptococcus. These intermediate types had been found in a wide variety of lesions, and might be of clinical importance in so far as they might be associated with certain definite clinical types of infection. Discussing the question as to the constant presence of the pneumococcus in the blood during lobar pneumonia, it was concluded, from a review of the literature, that the pneumococcus was demonstrable in the peripheral circulation, in practically every case, provided that fluid media and blood in sufficient quantity were employed. As to the question of the bactericidal action of pneumonia blood, it had been shown that this was due entirely to phagocytosis, and not, as had been supposed, by some, to bactericidal substances in the serum. Pneumococci might be readily grown in both normal and pneumonic serum. The production of acid by pneumococci when grown in pneumonic serum, as observed by Rosenau and Longcope, was of considerable theoretical interest. It was probable, in the first place, that this production exerted a deleterious influence upon the viability and also upon the virulence of the pneumococci during the course of a lobar pneumonia. Since virulent strains in test-tube experiments were known to resist phagocytosis, it was highly probable that such an attenuation of virulence must occur towards the end of the disease. Moreover, the marked and sudden increase in opsonic substances in the serum which was observed coincidently with the crisis, would be quite without significance did we not suppose that the pneumococci, having lost their original virulence, had been rendered susceptible to phagocytosis. Acid production by the pneumococci growing in pneumonic serum was of interest also from another point of view. Opie, working with sterile inflammatory exudate, produced by the injection of aleuronat into the pleural cavity of dogs, had shown that suspensions of washed leucocytes, when incubated for several days under toluol, underwent marked proteolysis, the proteolytic ferments being contained within the leucocytes. This autolysis of washed leucocytes *in vitro* took place with equal readiness in a slightly acid or alkaline media. When, however, serum, either from the exudate itself or from the blood, was added to the suspension of leucocytes, autolysis was distinctly inhibited. This inhibitory influence of the serum Opie ascribed to certain substances which he called antiautolysins. These anti-

bodies upon investigation proved to be efficient in checking self-digestion of the leucocytes only when acting in an alkaline or neutral medium. When the reaction of the serum was brought to an acidity of 0.2 per cent. by the addition of acetic acid, the autolysis of the leucocytes was no longer restrained. The application of these facts toward an explanation of the process of resolution in pneumonia was very tempting, and had suggested to Dr. Pappenheimer the following theory: One had but to suppose that the pneumococci, growing in the lung, acidified the serum in sufficient degree to annul its normal inhibitory influence in checking the autolysis of the leucocytes. As soon as this degree of acidity was reached, the intracellular ferments within the leucocytes exerted their proteolytic powers, and as we might say, the "exudate resolved or digested itself." This explanation of the phenomenon of resolution was, of course, entirely speculative and was offered merely to point out the interesting field for experimental research opened up by Rosenau's observation. Wolf's recent work upon the behavior of the opsonins in lobar pneumonia was reviewed; also his preliminary work on the treatment of lobar pneumonia with heated bacterial cultures after the technique of Wright. The results, so far as they went, appeared to be encouraging, since the crisis occurred in the majority of cases on the third or fourth day, and the total mortality of a small series of cases selected at random was far below the death rate during the same month of cases of lobar pneumonia treated in other ways.

Dr. E. LIBMAN discussed this paper.

Extrapulmonary Pneumococcus Infections.—Dr. JOHN S. THACHER read this paper. He said that during the twenty years since Fraenkel and Welchselbaum showed that this diplococcus was the usual bacterial factor in producing pneumonia, observations had gradually accumulated showing that not only the lungs but all parts of the body were at times attacked by the pneumococcus and often with disastrous results, and therefore it was at last recognized as ranking with the virulent staphylococcus and streptococcus as a pyogenic germ. Its power of invading all parts was enhanced by the readiness with which it entered the circulation. It had been reported as found in the blood in cases of bronchitis, edema, and congestion of the lungs, catarrhal inflammation of the nose and its sinuses, cholecystitis, phlebitis, abscess of the finger, and multiple superficial abscesses. It had been found in the milk and urine in cases of pneumonia. The pneumococcus had appeared as the sole infectious agent present in inflammations of all parts of the body. Dr. Thacher then recited a list of lesions which had been recorded in the medical literature as shown to be due to an infection by the pneumococcus. He condensed the enumeration of experiments and said that the pneumococcus was prone to excite inflammation of the respiratory organs, including the pleura and the upper air passages and the cavities connected with them, of the eye, the meninges, the heart and veins, the peritoneum, the kidneys, and the bones and joints, also abscesses of various parts and general septicemia. The conclusion was fully warranted that though less so than the lung and pleura, still in a high degree the pericardium, endocardium, and meninges furnished favorable soil for the mischievous development of the pneumococcus. The upper air passages and their adnexa, especially the middle ear, were also very frequent sites of pneumococcal inflammation.

Dr. JOSEPH A. KENEFICK said that this subject was most interesting to him as an otologist. Dr. Thacher had referred to the middle ear cavity as a region for the cultivation of the pneumococcus and he wished to call attention to a book on otitis, published in Leipzig last year, in which a report of 100 autopsies on children under two years of age was made and the statistics were of broad application and threw considerable light upon the activity of the pneumococcus in young children. There was a form of otitis, otitis concomitans, which occurred in marasmic children, and the middle ears of these children were filled with cultures of the pneumococcus. Out of 100 autopsies—200 ears examined—there were 121 infected cavities; of these 121 infected cavities 112 had a mixed pneumococcic infection and in 96 the pneumococcus was obtained in pure culture. In reference to the cause of meningitis, 60 per cent. of all cases of lepomeningitis were said to be due to the presence of the pneumococcus. Therefore, in meningitis they had first to deal with a pneumococcus in pure culture; the pure culture could be obtained as well from the fluid of a lumbar puncture.

Dr. FRANCIS P. KINNICUTT asked if the prognosis in otitis was more favorable in a pneumococcic infection than in the streptococcic.

Dr. KENEFICK replied that streptococcic infection of the middle ear was accompanied by a high temperature as in streptococcic infections elsewhere. Whereas in pneumococcic infection the condition could go on with apparently no evidences of destruction of bone, etc., and without any temperature or pain. Yet when the mastoid was uncovered it was found that the destruction of bone was out of proportion to the symptoms presented. Here one met with the most extraordinary destruction of the inner table, the lateral sinus was covered with granulation tissue, and yet little or no sign of the condition was presented. One could not rely upon the temperature.

Observations on Arteriosclerosis.—Dr. H. NEWTON HEINEMANN presented this communication. He said that arteriosclerosis was a disease of exhaustion and not of age, and it was important that we should know how to maintain the circulation. In considering the etiology there were external and internal agents. The disease occurred after 45, but mostly after 50 years of age. The male sex was more subjected to it. Inheritance was a predisposing cause, as well as mental worry and strain. Neurasthenia, gout, and rheumatism should be looked upon as etiological factors. An acute attack of gout or rheumatism might start an attack. Typhoid fever had been clearly established as having an influencing effect. Influenza was one of the most common causes of a breakdown. Scarlet fever, diphtheria, and other exanthemata often furnished the early beginning of cardiac and vascular changes. The effects of autointoxication from toxins could not be overestimated. Alcohol, tea, coffee, and drug habits were influencing factors, depending upon their abuse. Lead poisoning was a common cause. External suppurations inaugurated changes, and head injuries were both predisposing and exciting causes. The mental and physical strain in attaining success also acted as a cause. In considering the pathology he divided the cases as follows: (1) the occupation and senile type, generally of the extremities, with well-marked calcific changes; (2) the syphilitic type, with well-marked lesions usually leading to aneurysm; (3) the renal type; (4) myocarditis, with embolism and death often following; (5) the miscellaneous group with moderate sclerosis in various parts of the body; any set of arteries might be involved. The senile and the working type went together. He spoke of an instance occurring recently in Germany in which a man was operated upon; his femoral artery was as stiff as a pipestem and this was not noted until the operation. In the renal type one found the well-known changes in the urine with the marked hypertrophy of the left ventricle, and often death from cerebral hemorrhage. The syphilitic type was one by itself, and demonstrated the fact that the changes went on in segments. There was also the peculiar narrowing of the vessels, due to thickening of the walls, particularly where branches were given off. The circulation was slowed and the toxins got a chance to work at that site. He spoke of the case of a man thirty-eight years old, who died after symptoms of acute infection lasting only ten days. It was found that he had a periarteritis nodosa syphilitica, and these cases he said should always

be looked upon with suspicion. He showed a chart of gastric arterial sclerosis, this often occurring from autointoxication. There were often indigestion and pains, and these were dependent upon the sclerotic changes taking place in the arteries of the mesentery. He believed that many ulcers of the stomach and duodenum could be explained only by a thrombus in the sclerotic artery. He showed specimens to demonstrate this fact. Arterial sclerosis might begin in the arteries as an acute arteritis locally; after this a general arterial sclerosis might set in. This form was not a continuous lesion, beginning in one part and going from one place to another seriatim, as in syphilitic arterial sclerosis. It jumped to different parts and there was a tendency for it to appear bilaterally. It was not a progressive disease going from one end of the circulation to another. The pathological changes taking place in the arteries were not yet definitely determined, but according to the best opinions the changes took place as follows: In the first place there was a change in the stellate cells and interstitial tissue, these undergoing a fatty degeneration. Connective tissue formed and then a little cicatrix was left; this might be so small as hardly to be seen. This was what occurred in a characteristic arterial sclerosis. Marchand stated that streaks of fat were to be found in the intima in cases of anemia and mild infections, which disappeared entirely upon recovery. Dr. Heinemann believed that that had no special connection with arterial sclerosis. In arterial sclerosis the aorta was most commonly affected, then came the renal vessels, next the cerebral vessels, and then the mesenteric. The diagnosis was based upon the history of an old infection, such as some unusual mental or physical strain, abuse of stimulants, etc. In considering the diagnosis he emphasized the importance of preaching the doctrine of hope. With regard to treatment, during the past four or five years in scientific Germany he had heard distinguished gentlemen speak of iodide of potassium as though they had discovered its use. Dr. Alonzo Clark preached this twenty-five years ago and Trousseau fifty years ago. Iodide of sodium did not take the place of iodide of potassium. The Germans seemed to have an antipathy to nitroglycerin in arterial sclerosis, but he continued its use. In speaking of the bath treatment he said that there was no doubt that many men came to Nauheim condemned to death, and yet they might live for years and in comfort. He emphasized the importance of taking autointoxication into account in the treatment of arterial sclerosis; when a patient went to pieces with arterial sclerosis it was from the autointoxication, and it became very dangerous when the patient was permitted to become constipated.

Dr. George L. Peabody, speaking of the youthful cases, said he had notes of two patients, aged nineteen and twenty-one respectively, whom he had followed to the death and autopsy. In both the arteries were extensively diseased, and both died from cerebral hemorrhage. In his experience most cases of periarteritis he regarded as syphilitic. It was interesting how frequently a marked general arteriosclerosis was accompanied by changes in the vessels at the base of the brain. In the treatment of arterial sclerosis there was too much of a tendency to pay attention immediately to the arterial tension; for instance, arterial sclerosis was compensatory in nephritis; the hypertrophy of the left ventricle was compensatory in the development of a nephritis, and he believed it was a mistake in every case of increased arterial tension always to lower it. If there were no symptoms, and the patient was excreting a reasonable amount of urine of good specific gravity, the patient should be watched, but the tension should not be lowered below the normal, as was so frequently done. A great deal of harm could be done by the indiscriminate lowering of the arterial tension in cases of arteriosclerosis with nephritis. In speaking of arterial spasm, he referred to the case of a patient suffering repeatedly from attacks of partial hemiplegia, occasionally the hemiplegia being complete, but without loss of consciousness. The patient would recover and be up and about in an hour from the onset of the attack. He followed this patient to his death. In his last attack he lost consciousness and had all the symptoms of a cerebral hemorrhage. Autopsy was immediately performed, and in less than one hour after death he had the brain, and found the most extensive arterial sclerosis of the arteries at the base of the brain, without any change whatever in the brain tissue. In this case there was a spasmodic contraction of the arteries which shut off the supply to limited areas of the brain, especially in the middle cerebral artery. In the last seizure the contraction had been so long as to be incompatible with life, and yet not long enough to produce any softening. This spasmodic contraction had been shown by the retinoscope time and again.

Dr. Francis P. Kinnicutt said that Dr. Heinemann had only indirectly referred to a potent cause of arteriosclerosis, viz., arterial hypertension. A justifiable difference of opinion exists in regard to the pathogenesis of arterial hypertension. The respective theories of an obliterating endarteritis of the small arteries and of vasomotor constriction of toxic origin, had each their adherents. A general consensus of opinion, however, prevailed in regard to the ultimate influence of chronic arterial hypertension, if the term may be used in this connection, in causing pathological changes both in the heart muscle and in the vessels. In this connection Dr. Kinnicutt called attention to the importance of not mistaking apparent for real hypertension. By apparent hypertension is meant a high systolic pressure with a subnormal or normal diastolic pressure, which would give a normal or a slightly increased mean pressure. Referring to Dr. Heinemann's remarks about the sphygmograph, the speaker said that after a period of some confusion in regard to the knowledge to be obtained from it, of late the knowledge seemed to him to be of a distinctly more definite character. One could not fail to be impressed with the work of Mackenzie of Burnley in this field. At the meeting of the British Medical Association at Toronto he emphasized the possibility of differentiating the various forms of cardiac disability associated with arterial hypertension. By sphygmograms one might differentiate apparently the heart failure due to failure of the function of tonicity, of which dilatation was a manifestation. Again it might be possible to recognize by the kind of arhythmia a disturbance of function in the auricular ventricular connecting muscle bundle of His, and finally, in the true pulsus alternans, failure in the function of cardiac contractility might be recognized. All these forms of cardiac disability might be and usually were associated with arterial hypertension, but should be referred to a disturbance of different functions of the heart muscle.

Dr. L. F. Bishop said that the lesson to be learned was that the bad arteries that behaved well were not so bad for the patient as the better arteries which behaved badly. Diseased arteries might behave so well that the patient could get along and fill out a fair measure of life; under careful therapeutic measures; even with high arterial tension and bad arteries, the patient might live fairly comfortably and have a happy existence, even doing a certain amount of work. He did not agree with the statement that iodide of sodium was not so useful as iodide of potassium; in cases of high arterial tension it seemed to him that it did better and the clinical results were more satisfactory.

Dr. H. P. Loomis thought that all used nitroglycerin, but personally he had few results from it, although he still used it. Iodide of potassium he considered better than iodide of sodium; the latter preparation was unstable and most unreliable. During the acute stages of arterial sclerosis improvement would be very rapid if the patients were confined to an exclusive milk diet, especially peptonized milk.

Dr. John J. Morrissey said that one of the interesting

manifestations of arterial sclerosis, from a life insurance standpoint, was found in the development of an interstitial nephritis. The mortality rate was very much higher, he believed, in America than abroad, and this was probably due to the strain and competition of American life. This was one of the greatest problems for their consideration in life insurance work, namely, the diagnosis of chronic interstitial nephritis; it was not easy to make such a diagnosis when the examiner saw the individual only once or twice. He said that practitioners should try to instill a feeling of hope in those afflicted with cardiac affections. Unless there was undoubted myocardial degeneration of the heart they should hold out hope to these patients, and while they could not entirely regain their strength, they might live for years. He asked Dr. Heinemann if he had ever found the colon bacillus a causative factor in the production of arterial sclerosis. Sir James Barr of London found many cases of arterial sclerosis dependent upon the colon bacillus, not as the sole factor, but as an associated factor in the development of the disease.

Dr. Heinemann, closing the discussion, showed specimens of arterial sclerosis and atheroma to show they were not different things. One was taken from a patient with syphilitic arterial sclerosis, thirty-eight years old; the other was removed from an old man of eighty-six years who had senile sclerosis, but with no calcific plates. In the man of thirty-eight death was from syphilitic arterial sclerosis, the thickening not being very great; the blotch shown was fatty degeneration or atheroma. It was interesting to note atheroma in a syphilitic artery in a man of thirty-eight; in the other there was atheroma in a senile artery in a man of eighty-six, with no calcific plates. There was no doubt of the influence of hypertension in the production of arterial sclerosis. His paper referred to cases of spasm; he had seen cases of angina which were caused by pure spasm. He recalled a woman, aged fifty years, who had "flushes"; they were simply attacks of angina. He also had seen anginal spasm of the hands, of the larynx (almost causing death from edema of the glottis) and other parts of the body in connection with arterial sclerosis. Among the local symptoms produced by arterial sclerosis was the intermittent limping that Erb and Charcot described. In answer to the question as to the colon bacillus being a factor in the etiology, he said it certainly had an influence. But one should not forget that there were many things that were factors. He agreed with Dr. Loomis in what he said about nitroglycerin in so far as the ultimate results were concerned. He warned against the use of beef tea, beef extracts, and the like. Most of these were colored by caramel, which sometimes produced autointoxication in the presence of sclerotic arteries. The beef tea was also a stimulant and did harm. Milk was a toxic agent in many cases when taken in the ordinary way. White meats [illegible] Vegetables, especially the green ones were useful. Potatoes might be allowed in small quantities. Rice might be given *ad libitum*. Bread should always be stale. No sweets should be allowed. There should be restriction of the amount of liquids, particularly at meal time.

Chicago Medical Society.

At a meeting held November 7, 1906, Dr. William Allen Pusey read a paper entitled "The Prevalence of Leprosy in North America and the Policy to be Pursued with Regard to It." He said there was a focus of leprosy in Tracadie, New Brunswick, a few cases among Norwegian and Icelandic settlers in the Central Northwest, and sporadic cases were found among immigrants on rare occasions in any part of the United States. The important foci of leprosy in the United States were on the Pacific coast, where it was introduced by the Chinese, in Louisiana, and in Key West. In both of the latter districts it was introduced from Spanish-America. A few cases originating in the United States outside of subtropical districts had been recorded. The only focus of leprosy which seemed to be of importance as regarded danger of spread of the disease was that in Louisiana. There the favorable influence which was afforded by climate made the development of leprosy not an uncommon occurrence. Leaving out of consideration Louisiana, and taking all facts into consideration, it might be assumed that there was practically no danger from the presence of a sporadic leper in any part of the United States. In districts like Louisiana, where leprosy was active, every effort should be made to segregate the leper as completely as possible; to that end public asylums of refuge for them should be provided, as had been done in Louisiana. These should be made as agreeable places of residence for the sufferers as possible, if for no other reason, in order that lepers might willingly accept these asylums. This did not demand a very high standard of comfort, for the outside world was not a very cheerful place of residence for a leper in an advanced stage of the disease. Such treatment as was accorded lepers commonly was a reflection on common intelligence, to say nothing of humanity. If, for example, the reports which he had seen describing the lazaretto, or, rather, prison for lepers in San Francisco, were true, the place was a disgrace to California. We were all familiar with the wretched exhibition of fear shown in the recent case of the Servian leper, who was shunted about and left to die uncared for when he might with perfect safety have been taken care of upon any almshouse farm. Whether anything more should be done than to provide a place of asylum for lepers depended upon the district. In Louisiana it was, he believed, highly desirable to segregate the lepers. In Minnesota, where the population was vigorous, living condition good, and the climate favorable, nothing more was necessary than to keep patients under reasonable surveillance and see that they did not live in squalor and dirt in close contact with other persons. But even in such a district public help should be extended to the victims as fully as possible, and a place of refuge furnished them when they would accept it. What should be done with the sporadic leper, who occasionally appeared in any of the nonleprous districts of the United States? He should be treated like any other patient suffering from an infectious disease of very slow course, and of the lowest degree of contagiousness. There was no reason why he should not be admitted into a general hospital or be treated outside, provided the same precautions were taken that should be carried out with tuberculosis. Dr. E. A. Fischkin reported a case of leprosy. The patient, a fruit peddler by occupation, was a native of Russia. He came from the Baltic provinces, near Riga, from a district where leprosy was endemic. He was twenty-six years of age and was twelve years in the United States, having lived in Chicago all this time. His illness dated from April, 1905, up to which time he was healthy and never had any skin diseases. If his statements were to be believed, he must show an incubation period of at least eleven years, a period not extraordinary in leprosy. The family history showed no hereditary taint in the patient. His father died at the age of fifty-five from some acute disease which had lasted only three weeks. His mother was now sixty-one years old and was healthy. Three brothers and one sister were in good health. When a boy he attended the public schools of his native town. On questioning, he admitted having had some itching eruption on arms and legs at the age of fourteen, just before coming to America. It had lasted some three or four months, and while on the boat it had entirely disappeared, and he was perfectly well up to a year ago. Examination of the internal organs at the present time did not reveal any abnormal conditions. The patient, when first seen by Dr. Fischkin, looked very anemic; his pulse was weak; but there were no abnormal conditions of the heart; no murmurs. Spleen and liver were not enlarged; no adenopathy. A blood examination

showed hemoglobin, 95 per cent.; 5,200,000 reds to 10,000 whites. A differential count showed normal conditions. There were no plaques or ulcerations in the mouth, and the patient did not show any visible signs of rhinitis, and apparently no excessive salivary secretion. The eruption was mainly tubercular in character, and covered most of the unexposed parts of his body. The face was almost free of leprous manifestations. He could pass and was passing in the crowd unnoticed; but if you paid closer attention you discovered characteristic signs of leprosy. There was a circumscribed infiltrated area about 1 or 2 cm. on his forehead, thickened, overhanging eyebrows, which gave to the countenance a peculiar morose appearance, and was in this case a suggestion of what was termed the leonine face. The regions most affected were the extremities, the extensor surfaces of the arms, and the outside of the thighs. The arms were dotted with tubercles the size of a lentil to half a cherry. Most of them were rounded, of soft consistence, and a dark brown, coppery brown color. The larger ones were covered with slightly exfoliating thin scales. A few of the largest were deeply furrowed and looked almost lobulated. The smaller ones were flat, looked almost like syphilitic papules, but less hemispherical, very smooth and shiny on the surface, and showed a deep varnished or glazed color, as if they were covered with oil. The lower extremities were affected in like manner, though the lesions were localized more on the upper than on the lower leg. On the upper parts of the legs there were streaks of gyrated bands of infiltration running over the iliac crests to the back. The nates were covered with groups of characteristic tubercles. Above them in the lumbar region were large circinate infiltrations connected by somewhat irregular gyrate streaks and running out over the iliac crests to the anterior parts. The abdomen was for a long time free from manifestations, showing only a group of small tubercles near the umbilicus; but toward the end of the patient's stay under treatment there appeared suddenly a number of large, brown, somewhat raised, diffused areas of erythema leprosum or leprous roseola, which looked somewhat like a syphilitic roseola, the spots only being much larger, two or three inches in diameter, more mahogany brown in color, and infiltrated. Microscopical examination of an excised nodule showed large numbers of "lepra cells" and lepra bacilli.

Philadelphia Pediatric Society.

At a stated meeting held November 13 Dr. Eleanor C. Jones exhibited "A Case of Congenital Heart Disease." The patient was a boy, five years old, with clubbing of the extremities of toes and fingers and a systolic murmur at the pulmonary area, and another at the apex. The condition was supposed to be one of pulmonary obstruction and perforate ventricular septum. Dr. Jones exhibited also "A Case of Gonococcus Infection of the Mouth." The patient was a child, three years old, with gonorrheal vaginitis and urethritis, complicated by ulcerative stomatitis, resulting in destruction of a portion of the alveolar margin of the upper jaw and the loss of the central incisor teeth. There was no history of syphilis, and gonococci were found in the vaginal and urethral discharge, and also in that from the lesion in the mouth. Drs. H. Lowenberg and G. E. Pfahler exhibited "A Case of Cretinism," and also "A Case of a Cretinoid Condition," illustrated by *x*-ray pictures. The one patient was a girl of infantile appearance, nine years old, presenting other typical features of cretinism, in whom marked improvement, especially in the mental symptoms, took place after administration of thyroid extract. The second patient was a girl, ten years old, who presented a cretinoid appearance, somewhat suggestive also of Mongolian idiocy. The stature was diminutive and the eyes were somewhat almond-shaped. The mental condition, however, appeared excellent. Thyroid extract was administered in this case also, but without result. The *x*-ray pictures showed in both cases great retardation in the process of ossification, especially in the epiphyseal cartilages and the carpal bones, in less marked degree, however, in the case of the second child, presenting merely a cretinoid appearance. These findings are in striking contrast with those observed in cases of rickets, and also of syphilis, in both of which conditions the bones exhibit premature ossification. Dr. C. H. Weber reported "Two Cases in which the Edebohls Operation was Performed in Children," and he exhibited one of the patients. Both of the children had presented pronounced symptoms of nephritis not yielding to usual therapeutic measures. The improvement was marked, and in at least one of the cases it was thought the operation saved the life of the child. Dr. McCombs exhibited "A Case of Vincent's Angina." The patient was a girl, eight years old, who presented a sort of yellowish patch on one tonsil suggestive of diphtheric membrane, and removal of which left a bleeding surface, and eventually an ulcer. Bacteriological examination of scrapings from the tonsil disclosed the presence of the specific spirillum and the accompanying fusiform bacillus. Dr. M. Howard Fussell read a paper entitled "Artificial Feeding of Infants in General Practice." He pointed out the dangers, especially scurvy and rickets, residing in the use of artificial foods, and he described a plan for overcoming the difficulties in the way of prescribing scientific milk mixtures. This latter consists in having constantly with one tables indicating in percentages, and also in quantities, the proportions of proteids, fats, and carbohydrates, and of milk, cream, sugar, and diluents respectively, indicated at different times in infantile life and the total amounts and frequency of administration. Dr. Theodore Le Boutillier reported "A Case of Hysteroepilepsy." The patient was a girl, fifteen years old, who, following a fall from a moderate height, developed convulsive seizures recurring periodically. Recovery resulted under a course of treatment comprising a full measure of rest, a generous supply of appropriate food, and light outdoor exercise. Drs. D. J. Milton Miller and C. Y. White exhibited specimens from "A Case of Congenital Hydronephrosis, Dilated Ureters, and Hypertrophied Bladder in a Child Six Weeks Old."

Pathological Society of Philadelphia

At a stated meeting held November 22 Dr. P. B. Bland exhibited "A Uterus Containing a Large Chorioepithelioma with Metastases in Kidney and Spleen." The patient came under observation on account of uterine hemorrhage, and on examination a new growth was discovered involving the cervix. This was removed through the vagina and presented the histological appearances of a round-cell sarcoma. Some two months later there was recurrence of the bleeding, and the patient noticed the presence of an abdominal tumor. This was removed and proved to be a chorioepithelioma of the uterus. Following the operation the patient bled profusely and continuously from mouth and rectum for several days, dying practically exsanguinated. Dr. Alfred Gordon exhibited "Two Specimens of Cerebral Hemorrhage." One occurred in a man who had suffered a right hemiplegia earlier in life, from which he had almost fully recovered. In the final attack the patient presented a condition of euphoria, a state of mental contentment and satisfaction. After death an extravasation of blood was found in the left prefrontal region. The second specimen was obtained from a woman who died suddenly. Post-mortem examination disclosed hemorrhage into the lateral ventricle. Dr. F. H. Klaer presented a communication entitled "Blood-cultures in Typhoid Fever by Conradi's Method." Ten cases were studied with positive results in five; in the remainder the observations were made after the twenty-fifth day.

Surgical Suggestions.

Skin Grafting.—Cannaday cuts and transfers his skin grafts dry without the use of any saline solution. He then covers the grafted site with thin dental rubber dam, one piece if the area is small, or with strips crisscrossed for drainage if the area is large. Place a small gauze pad over this, securely anchor it from all sides with narrow strips of zinc oxide adhesive plaster to prevent displacement of the grafts, and apply externally a cotton, gauze, and bandage dressing. In many cases it will be well to encase the part with plaster-of-Paris to secure immobility. A slight amount of pressure will keep the grafts in apposition with the part, will prevent serum from collecting between graft and wound and separating them, and will control bleeding; on the other hand, too much pressure will destroy every vestige of life in the grafts. The plain dry dressing as described above possesses the advantages of simplicity and neatness, renders the after-care less complicated, and can easily be removed when adherent by aid of the free use of peroxide of hydrogen and sterile water without disturbing the underlying epithelium in the least.

The Operative Sterilization of Women.—Friedemann suggests the following as being simpler than most of the methods proposed. The tube is crushed with some instrument of the type of the enterothriptor of Mikulicz and the resulting groove is ligated with catgut. The extreme compression totally destroys the mucous membrane, but the submucosa persists. Experience obtained in intestinal surgery shows that under these conditions a restoration of the mucous tube is entirely out of the question, as the seat of the trauma becomes converted into a solid scar of connective tissue.—*Zentralblatt für Gynäkologie.*

Painless Labor.—E. Lamphear describes his method as follows: When labor has progressed to the stage when the os uteri is well dilated and the pains are becoming distressingly severe a hypodermic injection of one-quarter of a grain of morphine and one-hundredth of a grain of hydrobromate of hyoscine may be given; in one hour the forceps may be applied and labor completed without any pain whatsoever, even though the perineum be lacerated and sewed up. There need be no hurry—the perfect analgesia will last for hours. If the patient is not asleep at the expiration of the hour after injection a few drops of chloroform may be given by inhalation—a dram at most usually putting the patient into a profound sleep of some hours' duration. There will be none of the nausea of prolonged ether or chloroform narcosis, no increased danger of postpartum hemorrhage (as after chloroform), and no necessity for a skilled assistant to give the anesthetic.—*Medical Recorder.*

Shock.—Beddard says that alcohol and ether used to be given in the treatment of shock in the belief that they were cardiac stimulants. It is now known that they are not, and, furthermore, a cardiac stimulant could be of no real value in the treatment of shock, because no increase in the heart's action can counteract the fall in arterial-blood pressure caused by loss of the peripheral resistance. We may, therefore, conclude that alcohol and ether are useless, and it is probably true that they are therapeutically harmless in the doses usually administered The pathology of shock makes it clear that the only useful drug would be one which raised the blood pressure by increasing the peripheral resistance, not through the vasomotor center, but by acting direct upon the peripheral arterioles; and in adrenalin we possess such a drug. Adrenalin given by the mouth to patients other than those suffering from Addison's disease has practically no effect upon blood pressure because it is not absorbed from the alimentary canal. In shock adrenalin must be given either subcutaneously or intravenously. Adrenalin given subcutaneously in therapeutic doses produces a temporary glycosuria, but is otherwise harmless. A safe dose for an adult is from 20 to 30m of a 1 in 1,000 solution. Its effect upon the blood pressure comes on within a very few minutes and has gone in about an hour, therefore the injection has to be repeated about every hour until the shock has passed off. Given intravenously, the effect of adrenalin is instantaneous and it does not last more than ten minutes. It is, therefore, necessary to infuse continuously a weak solution, such as 1 in 20,000.—*Clinical Journal.*

Purulent Nasal Discharge.—Mackie says that the essential cause of suppuration is defective drainage, and in childhood this is usually the result of the presence of adenoids and lymphoid hyperplasia. Later it is the result of hyperthrophies and deformities, resulting from lymphoid hyperplasias during the period of active growth and development. In chronic cases in adults a diseased ethmoid is often at the bottom of the condition.—*Journal of Laryngology.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.*

ILLINOIS STATE BOARD OF HEALTH.

October 17-19, 1906.

ANATOMY.

1. Name the three principal forms or varieties of fibrous connective tissue.
2. Of what layers does the blastodermic membrane consist?
3. Name the membranes investing the fetus. From what is each of them developed?
4. With what bones does the astragalus articulate?
5. From where are the cerebral arteries derived and what remarkable anastomosis is formed by these arteries?
6. What is the use of the right ventricle of the heart? What is the use of the left one?
7. What is the origin, insertion, action, and nerve supply of the rectus femoris muscle?
8. What ligaments connect the os innominatum and the femur?
9. What is the general nerve supply of all the viscera in the abdominal cavity?
10. What main branches are given off by the external iliac artery?

PHYSIOLOGY.

1. Describe circulation of lymph.
2. What ferments are found in the intestinal juice and give their action.
3. Name the bile salts. Name the bile pigments.
4. Name salivary glands and their ducts.
5. Give the blood supply of the stomach.
6. Give composition of blood and amount found in the body.
7. Describe the pancreas and name its secretions.

MATERIA MEDICA AND THERAPEUTICS.

1. Name four cardiac depressants and explain mode of action and therapeutic uses of one of them.
2. Name two vasodilators and give therapeutic indications.
3. Name one drug which dilates and one which contracts the pupil, mode of action and uses of each.
4. Give derivation, physiological action, dose and therapeutic uses of pilocarpin.
5. Physiological action and therapeutic uses of quinine.
6. Name one urinary antiseptic, give dose and therapeutic uses and indication.
7. Name one immunizing serum, dose, mode of administration and indication for use.
8. In case of general venous engorgement, what drugs would you employ and why?
9. Give action of absorbable metal upon the circulation; name one and explain its therapeutic uses.
10. Name three diuretics. Explain mode of action and give uses of one of them.

CHEMISTRY.

1. Complete this formula: $FeS+H_2SO_4=$
2. Complete this formula, give name of compounds and resultant compound: $Mno_2+H_2SO_4+2HCl=MnSO_4+$
3. Why do urates form deposits in joints and cartilages?
4. Of what elements are albuminoids principally composed?
5. What is the normal amount of urine in twenty-four hours? State the average specific gravity of normal urine and its variations under various conditions.

PATHOLOGY.

1. What are the pathological changes met with in enterocolitis?
2. Give the pathology of cirrhosis of the liver.

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any textbook on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the student with the general character of these examinations and to inspire him with confidence in the result of his trial.

3. Give the pathology of chronic gastritis.
4. Describe the structural changes that occur in tubercular joints.
5. What pathological conditions give rise to aphonia?

BACTERIOLOGY.

1. Describe fully the Klebs-Loeffler bacillus, giving its characteristics and methods of staining.
2. Describe the microorganism commonly present in characteristic lobar pneumonia.
3. Describe the gonococcus of Neisser, also give the media upon which it grows.
4. Give fully the procedure adopted in carrying out the Widal test.
5. What bacteria are associated with inflammation and suppuration?

ETIOLOGY AND HYGIENE.

1. Name three diseases caused by specific microorganisms, and name the microorganisms causing such.
2. What is the etiology of eclampsia?
3. Describe the principal methods by which tuberculosis is spread.
4. How do you manage a case of scarlet fever in order to prevent the spread of the disease?
5. How do we determine whether a certain organism is or is not pathogenic?

PRACTICE OF MEDICINE.

1. Diagnosis and medical treatment of ulcer of stomach.
2. Give the etiology, symptoms, signs, prognosis, and treatment of cirrhosis of the liver.
3. Give the etiology, symptoms, signs, dangers, and treatment of general arteriosclerosis.
4. Give the etiology, symptoms, signs, dangers, and treatment of thrombophlebitis of femoral vein.
5. Give the etiology, symptoms, prognosis, and treatment of bronchial asthma.
6. Give the diagnosis, dangers, and treatment of nasal diphtheria.
7. Give danger and treatment of pulmonary hemorrhage from lungs as complication of pulmonary tuberculosis.
8. Give etiology, symptoms, complications, and treatment of acute articular rheumatism.
9. Diagnosis and treatment of diabetes.
10. Give diagnosis and treatment of myxedema.

NEUROLOGY.

1. Give the diagnosis of paralysis agitans.
2. Give the diagnosis and treatment of neurasthenia.
3. Give the diagnosis of epilepsy.

SURGERY.

1. What is a carbuncle? Where is it usually situated? Give treatment.
2. What are the indications for amputation in gangrene of an extremity?
3. What are the cardinal symptoms of luxation or dislocation? What complications may attend dislocations and how is each met?
4. Give the etiology, usual termination, and treatment of local periostitis.
5. What conditions may give rise to continued symptoms after complete reduction of hernia?
6. Outline two methods of operative treatment for internal hemorrhoids.
7. Give etiology, symptoms, and treatment for epididymitis.
8. Describe the preparation of a patient for abdominal section from two days before to the time of incision.
9. Give the etiology, symptoms, and treatment of hydrocele of the tunica vaginalis testis.
10. Describe an operation for the treatment of tuberculous cervical adenitis.

OBSTETRICS.

1. Define the terms uterine souffle, funic souffle, fetal shock. Tell the cause of each.
2. Discuss the use of douches, or antiseptic douches, during pregnancy, giving their advantages and disadvantages and their indications and contraindications.
3. Describe the management of second stage of normal labor.
4. Give the symptoms, prognosis, and treatment of eclampsia.
5. Give the diagnosis of ectopic pregnancy.
6. Give the causes and treatment of inertia uteri or delayed labor.
7. What is the management of delay in labor due to impaction of the presenting breech?
8. Name at least three diseases in the fetus causing increase in size which may delay or interfere with labor.
9. Name the varieties of placenta previa. What is the treatment of placenta previa after the fetus is viable?
10. Give the etiology and treatment of post partum hemorrhage.

GYNECOLOGY.

1. Differentiate between a partial inversion of the uterus and a polypus of the uterus.
2. Give the etiology, symptoms, and treatment of a vesicovaginal fistula.
3. Give the etiology, symptoms, and treatment of pelvic peritonitis.
4. Give the nonsurgical treatment for inflammation of the uterine appendages.
5. What dangers may arise when an ovarian tumor is complicated by a pregnancy? Give treatment.
6. Discuss the systemic, topical, and surgical treatment of chronic endometritis.

LARYNGOLOGY AND RHINOLOGY.

1. Give the characteristic lesions in tubercular laryngitis.
2. Give pathology of acute rhinitis.

MEDICAL JURISPRUDENCE.

1. Differentiate between melancholia and mania.
2. Define and illustrate delusion, illusion, and hallucination.

PHYSICAL DIAGNOSIS.

1. Give differential diagnosis between lobar pneumonia and pleurisy with effusion.
2. What is hydronephrosis? Give cause.
3. What valvular lesion would be indicated by murmur loudest at apex and during systole of heart?
4. Give diagnostic symptoms of hydrothorax and pyothorax, differentiating the two conditions.
5. Give definition of ascites. Under what conditions does it occur?

OPHTHALMOLOGY AND OTOLOGY.

1. Give the etiology and treatment of plastic iritis.
2. What is the diagnostic value of the tuning fork in otology?
3. Name ten frequent causes of deafness.

PEDIATRICS.

1. How do the symptoms of malarial infection in young children differ from the same in adults and older children, and at what age are these symptoms found to differ?
2. What in your opinion is the chief danger that may occur either as a complication or a sequel to: (a) scarlet fever, (b) measles, (c) rheumatism, (d) whooping-cough?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

October 17-19, 1906.

ANATOMY.

3. The membranes investing the fetus are: (1) the amnion, derived from the ectoderm and mesoderm; (2) the chorion, derived from the ectoderm and mesoderm, and (3) a thin layer of the placenta, derived from the maternal uterine mucosa.

PHYSIOLOGY.

1. The lymphatic circulation is, strictly speaking, not a circulation at all; since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

3. The bile salts are sodium glycocholate and sodium taurocholate. The bile pigments are bilirubin, biliverdin, and urobilin; in gallstones there may be found, in addition, bilifuscin, biliprasin, bilihumin, and bilicyanin.

7. The secretions of the pancreas are the pancreatic juice and an internal secretion.

MATERIA MEDICA AND THERAPEUTICS.

9. Mercury is an absorbable metal. Its action on the circulation: In small doses it has a tonic effect; in larger doses it diminishes the number of red-blood cells, impoverishes the blood, and thus upsets the digestion, and disturbs the general nutrition of the body.

CHEMISTRY.

1. $FeS + H_2SO_4 = H_2S + FeSO_4$
2. $MnO_2 + H_2SO_4 + 2HCl = MnSO_4 + 2H_2O + Cl_2$

The names of the compounds are, in order: manganese dioxide, sulphuric acid, hydrochloric acid, manganese sulphate, hydrogen monoxide (or water), and chlorine (which is an element and not a compound).

3. The reasons assigned are: On account of the diminished alkalinity of the blood and tissue fluids of those parts, and the comparative slowness of the circulation in those parts, which, when the blood contains an excess of uric acid, causes a necrosis of the cells, and hence weakens their powers of resistance and lowers their vitality.

4. Albuminoids are composed of carbon, hydrogen, oxygen, nitrogen, and sulphur.

5. The normal amount of urine passed in twenty-four hours is about fifty ounces. The average specific gravity is about 1.015 to 1.025; it may vary from about 1.003 to about 1.040.

PATHOLOGY.

1. There are two important forms of cirrhosis of the liver, hypertrophic and atrophic. The following table (from Thayer's "Pathology") will assist in distinguishing them:

Synonyms. Charcot's, Hypertrophic, Unilobular, Hepatogenous, Biliary.	Laennec's, Atrophic, Multilobular, Hematogenous, Hob-nail liver.
Jaundice. Early and marked, bile often absent from feces.	Late and slight, bile usually present.
Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly.

4. The synovial membrane becomes thickened and edematous, and sometimes ulcerates; the joint cavity becomes filled with a serous exudate; the joint and synovial membrane are invaded by the tubercles, and the synovial membrane now becomes shiny, smooth, and nodular. Fringes of the synovial membrane spread over the borders of the articular cartilage, and become adherent to it; the cartilage becomes eroded and destroyed, and pieces of it become detached, leaving the bone denuded. The bone now is attacked by the tuberculous process. There may be adhesions, subluxation, erosion of the socket, or other joint deformity.

5. Aphonia may be caused by: (1) Paralysis of the recurrent laryngeal nerve, which may be central (as in bulbar palsy), or peripheral (due to pressure of an aneurysm or tumor of the mediastinum); (2) injuries and diseases of the larynx, such as inflammations, tumors, foreign bodies, or stenosis; (3) excessive use or misuse of the voice.

BACTERIOLOGY.

5. The bacteria associated with inflammation and suppuration are: staphylococcus pyogenes aureus, staphylococcus pyogenes albus, staphylococcus pyogenes citreus, streptococcus pyogenes; also sometimes the pneumococcus, gonococcus, bacillus coli communis, bacillus pyocyaneus, bacillus typhosus, and bacillus epidermidis albus.

ETIOLOGY AND HYGIENE.

5. To prove the pathogenicity of a microorganism, it is essential: (1) that the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

SURGERY.

2. In *dry* gangrene, the general rule is to wait for a line of demarcation, and then amputate high up; but in *senile* gangrene, if the patient is exhausted or sepsis ensues, the amputation should be done at once, and high up, without waiting for the line of demarcation. In *moist* gangrene, after the formation of the line of demarcation, amputate high up. In *traumatic* gangrene, if spreading, amputate at once, and high up, without waiting for a line of demarcation.

3. The complications that may attend dislocations are: fracture of the bone, rupture of blood-vessels or nerves, extensive injury to the soft parts, the capsule may be rent, or even torn away from the bone, the head of the bone may be bruised by impact against the edge of the socket, and bony prominences may be torn off.

5. (1) The anesthetic may give rise to vomiting; (2) the effect of the constriction may remain after reduction, and the intestine continue paralyzed; (3) this may be followed by inflammation, ulceration, perforation, peritonitis, toxemia, and death; (4) the presence of another hernia, not reduced; (5) recurrence of the same hernia; (6) reduction *en masse;* (7) reduction into a diverticulum of the abdominal wall.

OBSTETRICS.

1. The *uterine souffle* is a rhythmical, soft, blowing sound, synchronous with the maternal heart-beat. It is due to the passage of blood through the enlarged uterine arteries. The *funic souffle* is a sharp, whistling or blowing sound, synchronous with the fetal heart-beat. It is caused by some interference with the circulation in the umbilical arteries. *Fetal shock* is the discomfort experienced by the pregnant woman, due to the movements of the fetus in the uterus.

8. General dropsy, hydrocephalus, and spina bifida.

GYNECOLOGY.

1. In the case of *polypus,* the body and fundus of the uterus are in their normal position in the abdomen, a sound can be passed into the uterus, the uterine and cervical canals are not obliterated, the polypus does not bleed easily, and is not particularly sensible to pain. The *inverted uterus* shows:—absence of body and fundus from normal position, will not permit passage of a sound into uterine cavity, the uterine and cervical canals are absent, the inverted uterus tends to bleed easily, and is very sensible to pain.

4. As far as possible, remove the causes, correct bad habits (such as constipation, masturbation, excessive coitus), rest in bed, hot vaginal douches, tampons of ichthyol and glycerin or of iodine and glycerin, diet of a nourishing and easily digested kind, plenty of pure water to be drunk, general massage (unless contraindicated), such tonics and other medication as may be indicated by the general condition of the patient, hydrotherapy, and, in chronic cases, mild exercises, abdominal support by a binder, clothing so adjusted as to take pressure away from the abdomen.

5. The chief dangers are: pressure symptoms causing impaired respiration, twisting of the tumor on its pedicle, incarceration of the tumor in the pelvis, death of the fetus, difficult labor, and death of the mother. The treatment is to remove the ovarian tumor as soon as it is diagnosed.

LARYNGOLOGY AND RHINOLOGY.

1. The mucous membrane of the larynx is usually very pale; there may be a few dilated capillaries on one vocal cord; round cell infiltration, with the formation of giant cells, is quite pronounced; considerable edema is present; the epiglottis is swollen on its free margins, and becomes turban shaped; ulceration occurs in any part where infiltration has been found, and appears in several places as small superficial ulcers, which coalesce and form a large irregular ("mouse-nibbled") ulcer; this is apt to be covered with a grayish white exudate in which the tubercle bacilli may be found.

MEDICAL JURISPRUDENCE.

1. In both melancholia and mania there is a general perversion of the mental faculties, but the former is usually accompanied with more or less depression, and the latter with more or less excitement.

2. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind were mistaken for a voice telling a person to do a certain thing—that would be an *illusion.* If a person fancied he heard a voice

when there was nothing at all to be heard, that would be an *hallucination*.

PHYSICAL DIAGNOSIS.

3. Mitral regurgitation.

4. In *pyothorax* there will be found the general symptoms of sepsis, chills, fever high and irregular but persistent, pallor, the presence of leucocytosis, and on aspiration pus may be obtained. In *hydrothorax* there will be no fever, no pain, and the fluid is nonpurulent.

5. Ascites is an accumulation of serous fluid in the peritoneal cavity. It may occur in cirrhosis of the liver, chronic peritonitis, anemia, nephritis, heart disease, compression of the portal vein, or obstruction of the thoracic duct.

OPHTHALMOLOGY AND OTOLOGY.

3. (1) aural polypi, (2) inflammation of the membrane lining the Eustachian tubes, (3) inflammation of the middle ear, (4) inflammation of the internal ear, (5) disease of the auditory nerve, (6) perforation of the membrana tympani, (7) parotitis, (8) diseases of the throat, blocking up the end of the Eustachian tube, (9) certain drugs, as salicylic acid, quinine, etc., (10) impacted cerumen.

PEDIATRICS.

2. (*a*) otitis media; (*b*) bronchopneumonia; (*c*) endocarditis; (*d*) bronchopneumonia.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	January	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	January	8
Arkansas*	F. T. Murphy, Brinkley	Brinkley	January	7
California	Chas. L. Tisdale, Alameda	San Francisco	Dec.	18
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	January	1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March	12
Delaware	P.W.Tomlinson, Wilmington	Dover	June	18
Dis. of Col'bia	W.C.Woodward, Washington	Washington	January	10
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta	April	—
Idaho	J. L. Conant, Jr., Genesee	Boise	April	2

Wisconsin	J. V. Stevens, Jefferson	Milwaukee	January	8
Wyoming	S. B. Miller, Laramie	Cheyenne		

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Utah.—At the next session of the Legislature there will be presented a new Medical Practice Act, to replace the one now in force, which dates from 1898 and is unsatisfactory in many respects. The new act is largely based on the laws of other States where the several features have been found satisfactory. Provision will be be made for reciprocity with other States whose requirements are equal to those of Utah.

Oklahoma.—At the September examination there were thirty-three applicants; of this number eleven failed, and twenty-two passed.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending December 8, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	356	162
Diphtheria	276	32
Measles	155	5
Scarlet Fever	149	9
Smallpox	13	—
Varicella	147	—
Typhoid Fever	72	15
Whooping Cough	52	10
Cerebrospinal Meningitis	8	2
Malarial Fever	.....	.....
Totals	1228	235

Ectopia of the Testicle.—Coudray declares that young children should be carefully examined for ectopia of the testicles. In early life external maneuvers for bringing about descent of the testicles if applied with persistence give excellent results up to the age of ten or twelve years. A bandage is a necessary help in the treatment. The external manipulations may succeed even in abdominal ectopia, as the writer has observed in a boy of eleven years. After the age of eleven or twelve years operative interference is generally necessary. The coexistence of a small hernia does not necessarily demand operation by the knife in very young children, but after six or seven years operation on the testicles with radical cure for the hernia is indicated in the majority of cases.—*Le Bulletin Médical*,

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 7, 1906.

Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 70, No. 25. Whole No. 1885. NEW YORK, DECEMBER 22, 1906. $5.00 Per Annum. Single Copies, 10c.

Original Articles.

SOME NOTES ON THE DIAGNOSIS AND THE RESULT OF SURGICAL TREATMENT OF CEREBELLAR TUMORS.

By B. SACHS, M.D.,

NEW YORK.

NEUROLOGIST TO MOUNT SINAI HOSPITAL; CONSULTING ALIENIST AND NEUROLOGIST TO BELLEVUE HOSPITAL, ETC.

THE question of the surgical removal of cerebellar tumors has given rise to considerable discussion. The difficulties of diagnosis are somewhat greater than those commonly met with in the case of other intracranial neoplasms. Not infrequently the diagnosis is made by exclusion, and strictly localizing symptoms are less certain than they are, for instance, in the cases of tumors affecting the motor or occipital areas. The peculiar position and the safe intrenchment of the cerebellum have rendered every attempt at interference more difficult and more hazardous than is the rule with tumors situated in the cerebrum. During the past few years I have seen twenty-two cases, sixteen in hospital,* and six in private practice.

The recent writings of Stewart, the symposium on this subject by Philadelphia physicians, the still later article published by Putnam (*Journal of Nervous and Mental Disease*, May, 1906) would seem to make any further consideration of this subject almost useless. But the more one sees of brain surgery in general, and of cerebellar surgery in particular, the more one becomes convinced that the report of single successes leaves an incorrect impression upon the minds of medical men. The successes are, after all, the exceptions, and if a true account is to be rendered of what can be expected from cerebellar surgery, the entire experiences of one or more men must be detailed without fear and without prejudice. It is necessary to speak of failures just as frankly as of the few cases which succeed tolerably well. Of the twenty-two cases above referred to, operative interference was urged in only seven of them. Among these the tumor was correctly located (as was proved by autopsy), but not found at time of operation, in two cases. The first of these cases was reported with great care in the second volume of the Mount Sinai Hospital Reports (p. 108) by Dr. H. W. Berg, and was also referred to in the report of the surgical service of Dr. Howard Lilienthal (p. 387). The facts of this case, briefly told, are these:

CASE I.—H. H., Russian, 36 years of age. Admitted August 22, 1900. Seven days prior to admission, severe frontal headaches over right eye chiefly; three weeks previously increasing tinnitus in left ear, accompanied by deafness on that side; daily vomiting. Vertigo in walking. Objective symptoms were: Slight dragging of right foot; no other weakness in legs; no ataxia of lower extremities. Both knee-jerks increased, right greater than left; no Kernig sign; no ankle-clonus. No ataxia of upper extremities, but slight weakness of right upper extremity. Face slightly flattened on left side. Ocular movements normal. No deviation of tongue; numbness of left side of face. Left mastoid seemed painful on pressure. Dr. Koller excluded mastoid disease, but found moderate double optic neuritis. Medical treatment was given a conscientious trial; no change in symptoms, except that weakness of legs and cerebellar titubation became more marked. I was asked to examine the patient on September 16, and again on September 28. Symptoms as above; in addition there were present at this time slight lateral nystagmus on extreme lateral movements of the eyes; some vertical nystagmus. Both recti externi deficient. Grasp of both hands weakened, especially of left hand. Diminution of sensibility to touch and pain on left side of face. Slight ataxia in left upper extremity. Slight cerebellar titubation. Knee-jerks active. Diminished power of resistance on firm closure of the left eyelid as compared with the right. Diagnosis, cerebellar neoplasm in left half of cerebellum. Operation was done by Dr. Lilienthal, October 5, 1900, in a most careful manner. "A large Omega scalp and bone flap, its base downward, was made over the left occipital region," the "dura was freely incised, and an excellent exposure of the cerebellum obtained with plenty of room for manipulation. . . . Hemorrhage was insignificant. After several aspirations of the cerebellum (some bloody fluid withdrawn—cyst?) the cerebellum was incised and the finger gently inserted for exploration. Result negative. Patient died about eight hours after operation." A "limited" autopsy (Dr. Mandelbaum) revealed: "in front of the left lobe of the cerebellum, within the dura, a firm, whitish tumor measuring about 4 cm. in all diameters. The tumor lies on the petrous portion of the temporal bone just over the internal auditory meatus. The pons is indented on its left side. The nerves at the base are pressed upon. Gliosarcoma."

No case could have illustrated more convincingly the difficulties encountered in cerebellar cases. I quote from Dr. Lilienthal's self-criticism: "The diagnosis having been well-established . . . . the exploration of the cerebellum should have proceeded until some satisfactory exploration of the symptoms . . . . had been encountered. Had the cerebellar tissue been cut away a little further, the tumor must have been exposed and *might* have been removed." There's the rub! The shock would have been still greater and the fatal issue just as certain. The moral is that, while every step in the entire course of the disease was most carefully considered the result was entirely satisfactory. The second case may be detailed more briefly:

*The full histories of some of the hospital cases will be published in a forthcoming volume of the Mount Sinai Hospital reports. The operations were done either by Dr. Gerster or by Dr. Lilienthal, to both of whom I am indebted for many courtesies.

Case II.—N. K., 17 years. Admitted December 19, 1903. Ill eight weeks with severe occipital headaches and almost daily vomiting, difficulty of speech, and unsteady gait with dizziness. During past four weeks, when headaches are worst, left arm "shakes," but no unconsciousness. During last week before admission both upper extremities felt "dead," the left more than the right. Examination:—Speech heavy, monotonous, scanning; pupils react sluggishly to light and during accommodation; ocular movements normal; "double optic neuritis with hemorrhages" (Gruening); uvula deviates to left; slight right facial paresis; gait, that of an intoxicated person, reeling always toward left side; no ataxia or spasticity; marked ataxic tremor of left upper extremity (psychical exaggeration); reflexes of upper extremities not increased; right plantar, left scrotal, both abdominal reflexes increased; no ankle-clonus; no Babinski. Diagnosis, tumor involving left half of cerebellum chiefly, some symptoms pointing to right side also. Operation was urged for the relief of pressure, with a faint hope that tumor might be reached. Patient was transferred to the care of Dr. Gerster, who operated upon him January 15, 1904. "Horseshoe-shaped incision over left half of occipital bone." Four punctures with needle in various directions, in the hope of striking more resistant mass, revealed nothing; "brain did not pulsate when dura was first exposed; at end of operation slight pulsation was visible. Patient's condition good during operation. About twenty minutes after patient had been returned to the ward, he began to breathe poorly, but pulse remained of good quality. Artificial respiration for fifty minutes stimulating enemata, camphor injections, oxygen, etc., without avail." Patient died evidently of direct respiratory paralysis, pulse remaining "fair" almost to the end.

Autopsy report: "Tumor about size of hen's egg, firm and lobulated, situated in posterior cerebellar notch, more on left side (¾ inches), compressing superior portion of vermis forward and to the right, causing a fold in the upper portion of right hemisphere; the tumor could be shelled out with ease, leaving quite a cavity in cerebellum. Sarcoma."

In this case, again, the localization was tolerably accurate; but even if the surgeon had been encouraged to remove much of the cerebellar tissue, the tumor could scarcely have been reached. The danger from hemorrhage would have been infinitely greater; as it was, the patient died from respiratory paralysis, probably due to secondary hemorrhage.

In one other case the author refused to urge operation; the patient was referred to another hospital, the operation was there attempted without success, and the patient died within a few days after the operation. In four cases a simple trephining operation was done over one or both lobes of the cerebellum; in these patients the operation was followed by marked improvement or, at least, temporary relief. In one instance the patient survived the first operation and succumbed to a second attempt to explore the tumor. In all the other patients in whom the clinical diagnosis of cerebellar tumor could be established beyond the shadow of a doubt, the operation was not urged, either because there seemed to be no possibility of finding the tumor, or because the tumor was supposed to be on the ventral surface, where one could not expect to reach it without incurring the risk of serious hemorrhage, or because the symptoms were too advanced, or were not so pressing that operative interference was imperatively demanded. One patient died suddenly on the day set for operation.

More than a year and a half ago, before the American Neurological Association, the writer reported upon this subject, and the publication of the article was withheld in the hope that further experience might possibly give better results. It is only fair to state that not a single one* of the twenty-two cases upon which these notes are based has been cured. Several have, however, been much relieved by operative interference, and, above all, impending blindness has in several instances been avoided by prompt surgical measures. In view of the alleviation which has been obtained, I shall be the last one to frown upon all surgical endeavors, but I cannot, on the other hand, concede that the removal of tumors of the cerebellum is a task upon which one can enter with a light heart and with any great hope of ultimate success. The results recorded by Horsley, Frazier, and others, will tempt every one of us again and again to advise operation in order to procure equally good results, but I must insist once more that if we are to judge of the matter fairly we must have complete statistics of successes and failures; otherwise we are bound to overrate the one and to underrate the others.

The symptomatology of cerebellar tumors has been so fully discussed by Dr. Mills (*New York and Philadelphia Medical Journal*, February 11 and 18, 1905; *University of Pennsylvania Medical Bulletin*, April and May, 1906) in his contributions to the symposium on this subject, that there would seem to be little to add to his statements. Cerebellar tumors present, first of all, the symptoms common to all intracranial neoplasms, viz., headache, nausea, and vomiting, double optic neuritis. As for the last it is to be noted that the optic neuritis appears almost invariably at an unusually early stage of the disease, that it leads with unusual rapidity, in many instances, to complete amaurosis, and that this physical sign is wanting less often in cerebellar than in other intracranial neoplasms. The intense headaches and the unusually rapid development of optic nerve changes have led me to advise trephining for the relief of pressure at the earliest possible moment in order to prevent complete amaurosis, and it is a satisfaction to know that in several instances blindness has been prevented and the optic neuritis has receded. A simple instance of this was the following case:

Case III.—I. R., 32 years of age, by occupation a tailor, who was admitted to Mount Sinai Hospital January 31, 1904, and discharged May 20, 1904. His illness had been of ten months' duration, and began with attacks of pain in the occipital region. At first he had two or three attacks of pain a day. At the time of admission to the hospital he had many such attacks. Vomiting was frequent, diplopia persisted, accompanied by flashes of light and pain in the eyes. His vision was rapidly diminishing. During the attacks of pain the patient could not speak. There was no motor paralysis and no sensory symptoms. His gait was typically cerebellar, and the patient exhibited a marked tendency to fall to either side; marked double optic neuritis with hemorrhages; distinct right-sided facial paresis; diminished grip in upper extremities with slight ataxia of both upper extremities; wrist reflexes and both knee jerks were increased, but there was no ankle-clonus or Babinski; hearing less on right side than on left; pupils were equal, action to light good, also during accommodation; ocular movements

*I admit that others have been a little more fortunate, though complete cures (not merely surgical cures) are rare indeed. In the discussion of the subject, Weir Mitchell, Starr, and others were inclined to share the writer's views.

were normal. On February 29 the patient had a general convulsion, was very weak, and vomited almost incessantly. March 11 a large bone flap was removed by Dr. Gerster in the occipital region, exposing both halves of the cerebellum. From this operation the patient made a good recovery, the headaches were distinctly lessened, the patient was able to walk better, and his eyesight remained stationary. On March 24 the second stage of the operation was attempted, the cerebellum was exposed, but the tumor could not be found. The dura mater was sewed up, the scalp wound closed, and after this second operation the patient made such excellent progress that he was discharged on May 20. He returned to his work and has been earning his livelihood ever since, his eyesight entirely satisfactory, his gait only a little unsteady, and his general health excellent.

In this case I believe that if the trephining had not been resorted to at an early day, the changes in the optic nerves would have rapidly progressed and blindness would have resulted. Such was the unfortunate result in a young girl who was seen in 1903, then eleven years of age, presenting all the marked symptoms of cerebellar neoplasm. A trephining operation was done to relieve pressure on January 4, 1904, and she had sufficiently improved on January 26 to be discharged from the hospital, but the disease had already advanced to such an extent that the double optic neuritis grew progressively worse, and although the child is still living—fully three years after she was first seen by me—she suffers less from headaches, but is bedridden, and has been absolutely blind for more than two and a half years.

Many of the patients with cerebellar neoplasm may live for years after the first symptoms appear, and in so many of them the optic nerve is threatened from the very outset that it is merciful to them to advise exploratory operation at the very earliest stage of the disease. There is practically no danger attending the cerebellar trephining operation (provided the surgeon will exercise a little care regarding hemorrhage), and the probability of blindness is so great that I would strongly urge that, if the patient present the marked symptoms of cerebellar neoplasm, and if the patient also exhibits the signs of a rapidly advancing optic neuritis, the attempt should be made in every single such instance to prevent the development of blindness by the surgical relief of pressure. In fact, other things being equal, rapidly advancing optic neuritis may serve as a symptom pointing to cerebellar tumor, for I have found this rapidly progressive form of double optic neuritis more regularly in cerebellar neoplasms than in tumors of the frontal lobe, and also more frequently than in cases of tumor in the temporosphenoidal region, or in the motor areas.

The early development of unilateral or bilateral rectus externus palsy is to be given due weight. I have been accustomed to regard it as almost pathognomonic of cerebellar lesions if it be associated with the general symptoms pointing to increased intracranial pressure. No doubt the peculiar position of the abducens nerve, the fact that it may be compressed very readily between the brain-substance and the base of the skull, will account for the frequent occurrence of this special form of palsy. An irregular lateral nystagmus is often observed in these cases on extreme outward movement of the eyes. This I hold to be due to the greater strength of the recti interni in the presence of weakened external recti muscles.

The authors on this subject are not yet agreed as to the importance to be attached to the side to which the patient sways in walking or standing. The evidence from my own cases would seem to be largely in favor of the patient swaying to the side in which the tumor is situated, but I would not allow any evidence of this sort to persuade me to determine the site of operation if other signs point to the opposite side of the brain. In several instances I have obtained much more valuable information as to the location of the neoplasm from the behavior of the facial nerve. Changes in the electrical reaction of the facial nerve often setting in before a marked facial palsy has been developed, have helped to corroborate a suspicion of cerebellar disease, and have pointed at the same time to the exact site of the neoplasm. This has been particularly true of tumors occurring in the cerebellar pontile angle. An instance of this I have reported more than ten years ago in the first edition of my book. The changes in the electrical reaction of the facial nerve may also occur with intracerebellar neoplasms on the side on which the facial nerve is affected. Early involvement of the auditory nerve is of similar value in determining the site of the neoplasm. If the progress of the disease is an unusually slow one, and if facial, auditory, and possibly trigeminal nerve symptoms are present; if, moreover, in such cases the symptoms are unilateral or bilateral, the diagnosis of a neurofibromatosis may be entertained. It is well to remember, however, that other forms of neoplasm (sarcoma in one of my cases) may occur in this very region, and may be of relatively slow growth, and may at times give rise to multiple lesions.

In view of the good results following upon prompt surgical interference in the cases here alluded to, it would be natural to state that much time is wasted by the routine administration of iodides and mercurials. In many cases this kind of treatment is adhered to merely to ease the conscience of the physician that he has given internal medication a fair trial before risking the life of the patient in his surgical endeavors, and yet, if I am to profit by my own experience, I must confess that in several instances much has been gained by this routine practice. Not many years ago Oppenheim reported cases of brain tumor occurring more particularly in younger individuals, who had the good fortune to get rid of all the symptoms at about the time set for the operation. In my own experience, exclusive of the cases here recorded, I have the records of three patients who presented all the symptoms of cerebellar neoplasm, such symptoms persisting for many weeks, and then, whether as the result of treatment or not, the symptoms subsided, and the patient practically regained normal health. In only one of these cases was there a distinct specific history. In the other two, one of them a woman, there was not a single reason to suspect specific infection, nor could there have been a shadow of doubt as to the correctness of the clinical diagnosis. In all three cases I entertained the idea of surgical intervention, and would have urged operation if the symptoms had not subsided within a few weeks from the time that treatment was begun. While I am, on the one hand, most anxious not to delay operation for fear of impending blindness, I am tempted, on the other, to be somewhat more conservative, and to give the patient the benefit of the possibility of spontaneous improvement, or of improvement due to drug treatment. In cases in which the headaches are intense, in which the gait becomes progressively worse and worse, and in which the optic neuritis is steadily increasing, in all such cases I believe it to be the better policy not to await the possibility of improvement without surgical intervention, but to advise

trephining as the first step toward a possible surgical removal of the neoplasm, and it is fortunate that we can nowadays undertake at least this operation without any material risk to the patient's life.

The difficulties of surgical interference are greatly increased because of the mere fact that in rare instances only can one predict with any degree of certainty the exact location of the tumor. In only four of the twenty-two cases upon which the conclusions of this paper are based was I absolutely certain of the cerebellar area affected. As recorded above, in two cases operated upon, the tumor could not be got at during the operation, but at autopsy they were disclosed in the exact position where they had been supposed to be. In another case the tumor was not found, despite the removal of a portion of the lateral lobe of the cerebellum, but the patient was so much benefited by the operation (evidently by the relief of pressure) that he was doing unusually well when last heard of—twenty-six months after the operation. Even tumors in the cerebellar pontile angle, easy to locate, are difficult to reach. Recent reports, more particularly those published by Frazier, have urged the removal of a portion of the cerebellum to get at cerebellar and cerebellar-pontile tumors. Some German writers (notably Borchardt) have been much impressed by this, and have insinuated that the lesser daring of German surgeons is responsible for the meagre results obtained by them in the removal of cerebellar tumors. I believe, however, that I am not the only one among the American neurologists who feels a peculiar aversion to the removal or mutilation of any part or area that is not distinctly diseased, and I for one should hesitate to advise such a procedure unless the symptoms point with absolute certainty to the presence of a neoplasm in a definite region, and unless there is also a tolerable certainty that when the tumor is found it will prove to be of such size and so conditioned that it can be removed. It does not ease one's conscience particularly to have removed a portion of the lateral lobe of the cerebellum, to come down upon the tumor, and then to find that the tumor cannot be enucleated. Moreover, it is well to remember that in cerebellar operations the danger from postoperative hemorrhages is greater than in the operations for the removal of other intracranial neoplasms. No doubt the proximity of the medulla oblongata has much to do with this, and not a few cases of cerebellar neoplasm that have been operated upon have died suddenly two or three hours or several days after the operation from causes "unknown or unsuspected."

I yield to no one in the desire for advance in brain surgery, but there will be little gained by claiming more than the facts warrant. At the present time cerebellar surgery is in a sad plight. Surgical measures will be resorted to in suspected cases, and it is probable that with the accumulating experience of years, provided such experience be recorded in full, we may succeed far better than we have in the past. The chief satisfaction that I have personally felt in my relations to cerebellar surgery has been in the prevention of blindness and the relief of headaches. I would strongly urge exploratory operation, palliative trephining, with this end in view. This has been well demonstrated in several cases in private practice, particularly in a girl now fifteen years of age, who is completely paralyzed as the result of a slowly growing cerebellar tumor. Her eyesight was threatened at the start, and yet has been preserved in consequence, as I firmly believe, of a large exploratory trephining, which was done primarily for the purpose of relieving pressure, and only secondarily in the hope of finding the tumor. Let me refer again to the patient thirty-two years of age, in whom the symptoms of cerebellar tumor were beyond doubt, who was operated upon twice, and in whom even at the second operation it was impossible to disclose the exact site of the tumor; great improvement has taken place since the operation, the man has been doing his work for two and a half years, is rid of his headaches, and his vision is satisfactory.*

While I firmly believe that the cure of cerebellar tumors is difficult to attain, except in a very small proportion of the cases, I believe that when the diagnosis of cerebellar tumor is made, and when there is a fair degree of certainty as to the special part of the cerebellum which is involved, a large trephine opening should be made over the suspected area; and, even if at the first or at the second stage of the operation the neoplasm is not found, much good will be done by the relief of pressure, the headaches will disappear, or will at least be diminished in severity, and blindness—the greatest of all scourges in these cases—may thereby be prevented or considerably deferred.

2. 1906.

CHRONIC URETHRITIS AND AN IMPROVED METHOD OF APPLYING MEDICATION TO THE URETHRA.†

By JAMES A. GARDNER, M.D.,
BUFFALO.
VISITING SURGEON GENITOURINARY DEPARTMENT, EMERGENCY HOSPITAL.

I DESIRE briefly to call your attention to certain exceedingly important conditions in cases of urethritis which are frequently overlooked and seemingly most difficult to eradicate. It is not unusual—in fact, it is quite common for the practitioner in his treatment of urethritis to find that the patient improves up to a certain point but continues to have the so-called "morning drop" or that shreds persist in the urine. He finds it practically impossible to get him beyond this stage. Both the patient and the surgeon become tired and discouraged and the patient drifts away. In examining for life insurance, shreds in the urine are often found although the applicant has believed himself perfectly cured. The symptoms referred to indicate that there still exists an inflammatory condition in the uretha. The inflammatory exudate may form a stricture. Under proper stimulus the discharge will return and the patient, ignorant of the danger, becomes a source of infection. I believe the method of treatment which I will describe will prove useful and efficacious in this class of cases. If it is used sufficiently early it will prove a preventative of the organization of the exudate and the formation of stricture.

The methods most commonly used in the treatment of subacute and chronic inflammatory conditions of the urethra are irrigations, passing of cold sounds, application of ointment by means of tubes and various shaped sounds, and packing the urethra with gauze impregnated with various medications. All these have their advantages and disadvantages, but the latter method has appealed to me for a number of years as the ideal one, if it could be used without irritating the patient. At first I used half-inch bandages and packed them through an urethroscope. Then Dr. Rucker's

* Word was received to this effect from the patient in December, 1906.

† Read before the Academy of Medicine, Buffalo, October

straight glass tubes came to my notice and the packing cord manufactured for use with them. These tubes and the packing cord proved much more efficacious than the former method, but could not be used in a great many cases. I found that the straight tubes were satisfactory in the pendulous portion of the urethra and although they could be used in the deeper parts, they caused too much irritation in the passing. To overcome this difficulty Jeffrey-Fell Company made for me some curved tubes which could be inserted into the deep urethra without any more damage to the inflamed surface than was occasioned by the passage of the straight ones in the anterior part (See Figure 1).

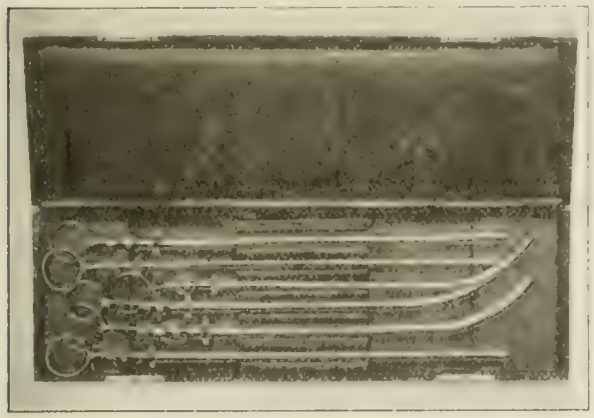

Fig. 1.

The glass tubes are of distinct value in treating subacute and chronic urethritis for the following reasons: they are easy of application and combine more valuable features than any other single remedy; the mucous membrane is stretched to whatever extent is desirable; the medication enters into the recesses and follicles where the organisms are usually protected from treatment or the urinary stream. The action of passing the instrument and the cord distending the walls of the canal hasten the absorption of the inflammatory exudate.

In case of a stricture in the formative stages from a granular patch or from localized inflammation, this is the treatment for curing the discharge and removing the shreds as well as preventing by its prompt absorption the organization of the exudate and the formation of stricture. If a stricture has already formed, the dilatation, with a local application to the mucous membrane to allay the inflammation and gentle massage at the point of constriction to increase the reaction, brings into action more factors towards its cure than any other single treatment.

Nodular masses and thickening of the mucous membrane are more promptly absorbed because the lymphatics and blood-vessels are toned up by the massage, cold, and medication. A great variety of medication may be applied by this method. The most satisfactory base of the medications I have used has been an oil, so that the patient upon removing the packing in from three to eight hours after treatment will find that it has not dried out enough to adhere to the mucous membrane. The patient is instructed to empty his bladder just previous to the treatment, the packing remaining in as long as he can go without urinating. He then passes a small amount of urine, which, as a rule, forces out the packing, though in some cases where it has been rather tightly packed he may need to assist by pulling gently on the end after it has been moistened by the urine. My method of inserting the packing is as follows:

I select a tube as I would a sound, according to the size of the urethra. If the condition is subacute I use a tube of smaller size, to cause as little irritation as possible in the passing. The cord consists of four strands. I use either two strands or the full size, whichever size fills the tube selected. The cord is then inserted in the handle end of the tube and forced through the tube by the obturator. As much of the cord is now pulled out at the distal end as is intended for use. (See Fig. 2.) If the localized inflammation or stricture is situated in the first three inches, I pull out three inches of cord; if it is further down the urethra, more is used. The cord and tube are placed in the medication until the cord is thoroughly saturated. The cord at the handle end is now pulled out until but an inch or so of the saturated part remains in the tube. The cord is then cut at the junction of the medicated with the nonmedicated portion. In pulling the cord through the tube it has acted somewhat as a piston and has drawn some of the medication with it. (See Fig. 3.) The tube is inserted and passed down the urethra beyond the area you wish to medicate. Because of the oily base of the medication no lubricant has been used. The obturator is then inserted into the cord near the distal end and pushed down the full length of the tube, carrying the cord with it, and at the same time forcing ahead into the urethra such medication with it. (See Fig. 3.) The tube is obturator is now withdrawn half an inch and pushed forward again; each time as the obturator

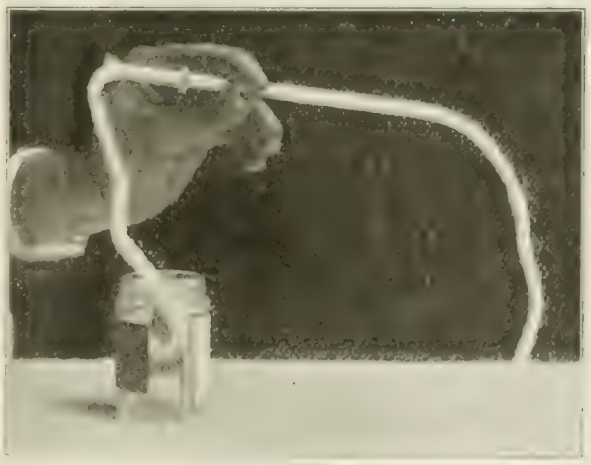

Fig. 2.

is pushed forward the tube is withdrawn the same distance. This leaves the cord in position. Force of any kind should never be used, nor is the treatment applicable in an acute condition. Unless this is borne in mind much harm can be occasioned by the use of this method at too acute a stage. The intervals between treatments vary according to the reaction which follows and the conditions being treated.

The following solutions have been found satisfactory in many cases, although, of course, various combinations may suggest themselves to the surgeon: Ichythol, one dram; resorcin, forty grains; balsam Peru, three drams; castor oil q.s., four ounces; lignol, one dram; balsam copaiba, one

dram; castor oil, one ounce; olive oil q.s., four ounces.

Chronic Urethritis and Gleet.—These terms have long been shown not to be synonymous, for a gleet may exist where a persistent search fails to show gonococci, and, on the other hand, chronic gonorrhea may not cause a discharge. Lydston divides these conditions into three varieties: (1) When the inflammation remains subacute with occasional acute exacerbations accompanied by more or less pain and smarting on urination, the prostate often being involved with a feeling of fullness in the perineum, together with frequent urination. (2) The discharge becomes thin and watery, being sometimes so scanty that nothing is visible, save a drop of mucopurulent fluid in the morning. This is the most frequent form, and depends upon: simple catarrh, involving constitutional and local predisposition; congested and granular patches of mucous membrane; organic stricture; abscesses or fistulæ; dilatation with chronic inflammation of the lacuna magna; chronic follicular prostatitis; urethral folliculitis; cowperitis; tuberculous infection. (3) A form of urethritis in which there is apparent recovery. After a variable period of time, a thin mucopurulent discharge develops as a consequence of sexual

Fig. 3.

excess or intemperance. The causes of chronic urethritis in a large majority of patients are inefficient treatment and excesses during the acute attack or the convalescent period; too early cessation of treatment, and the resumption of the ordinary modes of life, resulting in frequent relapses, each more stubborn than its predecessor; frequent repeated fresh infections, each attack being milder than the previous one but more prolonged. These conditions often leave submucous thickening and granular patches, and may lead to infiltration and subsequent sclerosis and contracture of the periurethral connective tissue—strictures. These are the most important factors in causing chronic discharge. The starting point is usually in the mucous depressions, where the inflammation persists and the organism is protected from the urinary stream, as well as urethral irrigations and injections. Here the gonococci lurk ready to increase their virulence at the proper stimulus. After a period of quiescence more or less complete, a stimulant is received in the form of congestion from dietary or alcoholic excesses, or sexual excitement, and what has been but a small, smouldering flame now assumes the character of a forest fire, and inflammation soon spreads to the adjoining urethra. Because of a certain amount of immunity of the tissues, having but recently been swept by this same flame, the length of time necessary to get it under control is not as long as in the primary attack, but each fresh attack increases the inflammatory condition of the mucous or granular patch, and assists in forming an organic stricture. Of 164 cases of stricture, Sir Henry Thompson gives the period of development as follows: Ten occurred during acute gonorrhea; 71 cases developed in one year; 41 cases in three or four years; 22 cases in seven to eight years; 20 cases in twenty to twenty-five years.

Duration of Contagion.—Johnson says, "If we were asked to define the most characteristic trait of gonorrheal infection, we would be obliged to say its tendency to persist and recur," but upon this point there is great diversity of opinion. Finger requires the absence of gonococci, pus corpuscles, and periurethral complications before allowing patients to marry. He believes that the newly-formed epithelial cells growing from the deeper layers carry the germs to the surface, and in this way tend to throw them off unless there is an acute invasion again of the deeper layers. Keyes is more liberal and allows his patients to marry when there is prolonged gleet of unknown origin, if no gonococci are present, and he believes it has a beneficial effect upon the discharge. White and Martin say it is safe to forbid coitus as long as gonococci can be demonstrated in the artificial acute cases from strong injections. The retention of a full-size sound for fifteen minutes, with massage along the urethra and prostate will usually aggravate the condition when gonococci are present if no attempt is made to destroy the organisms expressed from the follicles, and they are left in the urethra. Three or four glasses of beer usually increase the discharge to be examined. A patient should never be allowed to marry if gonococci can be found in the discharge or in the secretions massaged from the prostate, or in the semen collected in a condom during coitus.

Pathology.—The lesions usually appear as "intense congestions, excoriations, granulations, epithelial thickenings, papillomas, follicular, and lacunar involvement, or infiltration of the submucous periurethral connective tissue, resulting ultimately in a stricture." There may be a general leaky condition of the mucous membrane, due to some systemic weakness without any proof of localized inflammation. The most frequent cause is the glandular involvement with an exudate thrown out around the gland. Finger says that "chronic gonorrhea is essentially chronic inflammation of the subepithelial tissue, which passes through two stages, that of infiltration and contraction." Gouley says, remembering that a chronic mucopurulent discharge is nearly always a sure indication of the existence of a granular urethritis, which is the formative stage of certain strictures, the surgeon should direct his attention to the cure; if this is accomplished there will be no stricture.

All authorities agree that recent strictures can be cured by dilatation, therefore I claim that the treatment with the tube which dilates and also leaves a medicated dressing for hours in contact with the inflamed surface, not only cures the discharge, but will at the same time cure the worst complication that could arise—that of a stricture. The follicular involvement which is also constant

in these prolonged cases and which is so often the starting point of a stricture, can be massaged and the follicles freed from their secretion and filled with the medication. The massage and pressure are undoubtedly the most efficient means for removing the submucous and perifollicular exudate. This digression into the treatment is to emphasize the pathological points that are to be considered in the management of these cases, hoping that I may more deeply impress the importance of doing something for these patients instead of allowing them to continue an astringent injection or irrigation, taking balsams, etc., until the development of a stricture, with all its far-reaching effects. The epithelium of the urethra proliferates and degenerates, the cylindrical form changing to the squamous. The favorite seats are the posterior urethra and the bulb. The inflammatory process may be limited to the anterior or the posterior urethra, but usually involves both. The epididymis, prostate, seminal vesicles, and bladder may be affected.

Symptoms of Anterior Urethritis.—There is nearly always a history of recurrent attacks without sufficient reason. A slight discharge of mucus is generally present, but it may be of so small a quantity that it is seen only as the "morning drop." There may be only a stickiness at the meatus and yet the presence of shreds will show conclusively that the anterior urethra is involved. The discharge usually appears thin and watery, or whitish in color, until an exacerbation is brought on and it becomes more profuse, yellow, and thick, clouding the urine. Microscopically, it shows large number of pus cells, desquamated epithelium, intracellular gonococci, and other organisms in varying numbers. Shreds are invariably present in the urine, and are usually in proportion to the inflammation, and their decrease and final absence is a much better index to the progress and cure of the disease than is the discharge, for they persist long after the discharge has ceased. The shreds are analogous to the mucus that collects in the nasal cavities or the scabs which form on lesions exposed to the air where the serum and débris dry, but in the urethra they are washed out by the stream of urine. Their character varies from pure mucus which appears clear in color, often long and floating near the surface, to those loaded with pus, which readily sink to the bottom. Under the microscope they show mucus, pus cells, epithelium, gonococci, and other organisms, and should always be carefully studied in determining the diagnosis, prognosis, and treatment. There is usually some redness around the meatus, and slight burning may be felt on urination.

The symptoms of chronic posterior urethritis are unfortunately more or less vague and indefinite in mild cases, and it is these that are most dangerous in carrying disease to innocent wives. If urethritis is limited to the deep part of the canal, there will be no discharge, not even a "morning drop" to warn the patient of the danger. There is nearly always a history of a recurring discharge of varying degree of intensity from a mild, acute attack to a mere drop. These relapses are likely to be set up by alcoholic and especially venereal excesses, and usually yield promptly to treatment, the patient thinking many times he has contracted a fresh attack. There may or may not be a frequency of micturition which increases with the degree of urethro-cystitis. The desire to urinate is often imperative, and may be associated with pain in starting or completing the act. This may be a severe burning, with more or less straining to expel the final drop. If there is an acute exacerbation and the inflammation is marked, a drop of blood may be squeezed out of the congested verumontanum by the muscular contraction. The involvement of the sexual function is variable, and, as a rule, but not always, in proportion to the depth of the inflammatory process and the extent to which the prostate is involved. Ejaculations may be either premature or unduly prolonged or attended with pain. The normal sensation may be lost or altered. "So extensive is the nervous connection of the deep urethra and so depressing and widespread are some of the symptoms that it may be well considered the solar plexus of the pelvis." Pain may be felt in the lumbar or sacral region, down the thighs, above the pubis, or back toward the rectum. These pains may be mild and intermittent or dull and "uneasy" or neuralgic in character. Mental depression and neurasthenia are frequently seen, especially if nocturnal emissions are frequent. Indigestion, constipation, disturbances of the general health with loss of flesh are found in severe cases.

Diagnosis.—The histories of these cases are usually characteristic, shreds in urine constantly, a slight discharge if the anterior urethra is involved; no discharge if limited to the deep urethra, but recurrences are caused from alcoholic or venereal excesses when the patient thinks perhaps he is well. The discharge and shreds should be examined microscopically and strained for gonococci. In reaching a diagnosis not only locate the trouble, but determine if possible the cause of its persistence, as a urethral contraction, involvement of the prostate or any adjacent structures. Wolbarst's three-glass catheter test may now be used. Briefly, the test is as follows:

"The anterior urethra is washed out carefully until the washings come out clear—glass No. 1; this shows the condition of the anterior urethra. A soft, sterile catheter of small caliber is now passed into the bladder, and the bladder contents are drawn off into glass No. 2; this shows the bladder urine plus any possible drippings from the posterior urethra, or any possible urethral detritus carried in by the catheter; the catheter *in situ*, the bladder is washed out thoroughly, until the washings come out clear; this shows us that the bladder is empty of all pus or shreds; we now inject about eight ounces of clear fluid into the bladder, and withdraw the catheter; we have thoroughly washed out the anterior urethra and the bladder. The patient now passes two ounces of the fluid into glass No. 3; this shows us the condition of the posterior urethra. We therefore have obtained mechanically the separate fluids from the three portions of the urinary tract. If we decide to go into further detail, we may massage the prostate and have two ounces of fluid passed into glass No. 4; this will show the prostatic condition after massage." A bulbous bougie should be passed and any constrictions, tender points, or other abnormalities noted. A microscopical examination of the discharge brought out on the shoulder of the bulb is made. If the discharge has been persistent and ordinary treatment has failed, the canal should be explored with the urethroscope and a search made for congested or granular patches, etc. Some of these cases

have a persistence of shreds, but with symptoms so mild that frequently they are not noticed until perhaps a complication as impotence or prostatitis calls the patient's attention to these organs. Usually the sexual and urinary symptoms are well marked and point immediately to the deep urethra, although undoubtedly many of the patients are treated for cystitis by careless observers who do not examine the urine properly, a precaution so simple and yet very important.

Prognosis.—The time required to cure a chronic urethritis is usually in direct proportion to its duration and the complications. It is well never to promise to cure a patient in any given time, for there are so many factors under his control that may not be properly carried out, and then the surgeon is censured for failure to cure in the time specified. The average time for the cure of an uncomplicated urethritis is from three to seven weeks. Occasionally, however, there will be intractable cases, disappointing to both the surgeon and patient. If a stricture is beginning to form or is the actual cause of the discharge, the prognosis depends upon whether or not the surgeon realizes the importance of adopting a line of treatment to eradicate the inflammatory exudate while it is recent and soft. If it has undergone complete organization the prognosis as to the discharge is greatly altered, and it depends upon the curability and complication of the stricture. This is the most serious condition that could arise from a chronic anterior urethritis, and yet is often completely ignored in the management of these cases. If the deep urethra is involved all the factors in the case must be considered, such as age, general health, complications as prostatitis, cystitis, conditions of the kidneys and ureters, and here also is the question of stricture of great importance, the success depending upon attacking both simultaneously, as well as any other complication, if a prompt and permanent result is desired. The complication rather than the urethritis determines the prognosis. Dissipation, excesses, or irregular treatment will always prevent a satisfactory result.

Treatment.—No routine treatment can be used with these patients, but it must be selected after a careful examination of the anterior and posterior urethra, and a consideration of the previous history and treatment. The social condition, habits of the patient, and his general health are all important. The possibility of a stricture being the cause of a persistent discharge or the danger of the gleet resulting in a stricture must always be borne in mind. Fresh air, moderate exercise, nourishing but nonstimulating food, plenty of plain or lithia water are essential. If the patient has been overtreated the discharge will often cease if all treatment be stopped and the digestion and urethra allowed to become normal. Excessive sexual indulgence and excitement are always harmful. The bowels should be regulated by aperient waters or salines. Hot enemas alone or in conjunction with hot sitz baths may be found useful in certain cases, especially where there is a tendency to an irritable condition of the bladder. Oil of sandalwood and balsam of copaiba are probably the best drugs to use internally at this time, and they should be given in capsules. Methylene blue has also proved of service in these conditions. These drugs should be pushed to the full extent to obtain results. Many patients cannot take oil of sandalwood because of irritating nepthritic pains. In selecting remedies the milder ones are to be used first and the more radical measures adopted subsequently. For an uncomplicated anterior urethritis with only a slight mucopurulent discharge or a "morning drop" one may start the treatment with injections three times daily of a weak astringent solution. It should be strong enough to cause a slight smarting sensation, but not a positive pain. The latter generally means that some chemical violence has been done, which may be the starting point of a stricture by prolonging the inflammation. It is only by abuse of injections that harm results, for properly used they are very valuable in the treatment of gonorrhea, both acute and chronic. When given the patient should be instructed to urinate first and then the meatus should be held together for fifteen or twenty minutes.

Among the useful astringent solutions may be mentioned zinc sulphate 1-500, 1-100, lead acetate 1-500, 1-100, hydrastis muriate 1-500, 1-100. The strength of these should be increased gradually and the patient instructed always to dilute any injection that causes pain. If after two weeks' trial the discharge still persists, hot irrigations may be given once or twice daily of either potassium permanganate 1-4000, zinc permanganate 1-4000; silver nitrate 1-8000, or copper sulphate 1-10000.

In case the deep urethra or bladder is involved these irrigations may be forced back into the bladder, by having the patient relax the compressor urethra muscle by attempting to urinate. This treatment, unless contraindicated, may be continued for two or three weeks and if shreds and a discharge, or shreds alone, are found the urethra should be packed once a day after irrigation. If the reaction is excessive the interval may have to be increased to two, three, or four days. In some cases cold sounds passed followed by the packing is found to have a beneficial effect in stimulating the absorption of the exudate. After the first or second treatment, when the novelty has worn off, the patient having emptied his bladder previous to the packing is usually able to retain it from four to eight hours.

This treatment of packing the urethra makes it possible to apply to the inflamed portion a surgical dressing which remains there for hours in contradistinction to the usual injections or irrigations, which merely bathe the part for a few minutes. If used in the management of persistent discharge it is the most efficient means of preventing one of the worst complications that could arise—that is, stricture. All authorities agree that these soft, recent exudates may be absorbed before organization is complete. Therefore, this method is the most rational treatment for a prolonged discharge. This exudate is usually most abundant around the follicles, and, as the ordinary treatment has very little effect upon the deep infiltration, or the inflammation of the follicles, we have still further reasons for adopting this as a routine treatment of these cases. It is not to supplant but to supplement the other remedies.

Conclusions.—(1) The worst complication that is likely to follow a chronic urethritis is a stricture, consequently this should be borne in mind during the entire treatment.

(2) The pathology is essentially a chronic inflammation of the subepithelial tissue (and especially around the follicles), which passes through

two stages, that of infiltration and that of contraction.

(3) All authorities agree that these soft recent exudates may be absorbed before organization has set in. The most rational method of forestalling a stricture is by packing the urethra.

(4) The medication is in close contact for hours with the follicles and depressions, where germs are protected from irrigations and injections. The exudate thrown out around these follicles is frequently the starting point of stricture.

(5) No other treatment combines so many beneficial factors, *i.e.* dilatation, massage, medication uniformly applied to the entire membrane and depressions and for a considerable length of time.

THE GELATIN METHOD OF PRESERVING SPECIMENS.

By W. H. WATTERS, A.B., M.D.,

Professor of Pathology, Boston University.

On account of the large number of inquiries concerning the method employed by the Boston University School of Medicine in preparing the specimens recently exhibited at the meetings of the American Medical Association in Boston and of the British Medical Association in Toronto, this article has been written. Its aim will be to explain as fully as possible the origin, technique, and value of the method. The first description will be found in an article by the present writer that appeared in the *New York Medical Journal,* August 3, 1902. Several important changes have since been made that appear to require accurate description if satisfactory results are to be attained.

Before detailed consideration of the technique, a few preliminary notes may be of service in explaining why a new method was needed. As was pointed out in the original article, "certain things are essential to a satisfactory medium used in the preservation of specimens. It must prevent decomposition, conserve normal relationships with as little shrinkage as possible, and preserve the normal colors."

Let us consider how far the heretofore common methods reached to these requirements. *Alcohol,* one of the oldest of the preserving media, destroys color, causes much shrinkage, often macerates, renders thin membranes opaque, and rapidly evaporates. In some cases this may be satisfactory and adequate. Much more frequently, however, by bleaching all the tissues, it completely ruins the specimen to be preserved. *Formalin* was at first thought to be the long-sought-for color fixative, but the hopes so highly elevated were soon overthrown. To-day, much superior to alcohol, its place is recognized and its scope limited. When carefully used, it does not render thin tissues, as fetal membranes or the cornea, opaque; it fixes well, and in correct solutions does not cause objectionable shrinkage. The gas is very penetrating and objectionable to the oral and nasal mucosa, as well as to the skin. Many specimens can be excellently preserved in weak solutions which, when so prepared, require little subsequent attention.

Numerous other solutions might be mentioned, each satisfactory in a limited field, usually more used by the originator than by anyone else.

In addition to these, one more must be mentioned, as it is probably the one most widely used by the majority of modern museum workers. We refer to the Kaiserling method. Here the specimen is placed for a varying length of time in a solution containing a large percentage of formalin. By this means the hemoglobin is changed into methemoglobin, an insoluble substance of a brown color. Subsequent immersion in alcohol gives to the methemoglobin a red color, essentially the same as the original hemoglobin color, but now insoluble. The tissue is then placed in a solution of glycerin and potassium salts for permanent preservation. It may preserve a good color for years under favorable circumstances. Light will soon fade many specimens; others will become macerated by the preserving fluid, which also often becomes cloudy. Anyone who has had experience with glycerin will know how difficult it is to seal perfectly a jar containing this medium so that none will work its way out. And even in the most favorable cases the result is far from perfect from the standpoint of the demonstrator, a large, awkward jar, in which the specimen is rolling about at random. It is not necessary to enlarge upon this

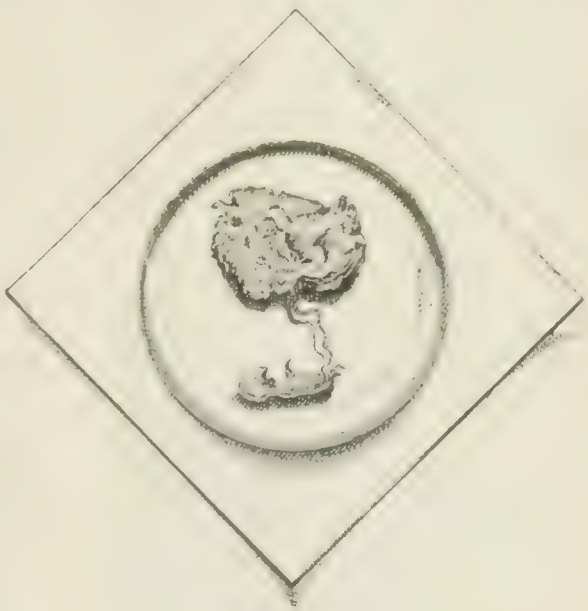

Fig. 1.

point to those who have tried to demonstrate pathological conditions under these circumstances. How much more desirable is a specimen firmly fixed in a solid medium, so that it can be turned upside down, or viewed from any side with ease. That some such solid medium might be advisable was long ago recognized, and a form of glycerin-jelly was suggested by Nettleship in 1871. This was used to a very slight extent, limited, as far as we are aware, to the preservation of eyes. It should be noted that no attempt was made to retain colors, the eyes being fixed in bichromate solution, and then placed directly in a carbolic-glycerin jelly. For general pathological purposes, therefore, the method possessed but few advantages over the more common media. Early in 1901 the writer, becoming much dissatisfied with all the then known methods, began a series of experiments that culminated in the process about to be described. This process has now successfully withstood the tests of nearly six years, has been adopted by many of the leading laboratories, and has received a very flattering amount of commendation from many of the best pathologists of the world.

The Method.—(It will be seen that the prelimi-

nary steps coincide accurately with the Kaiserling method.) Care should be taken to secure the specimen to be mounted in as fresh a condition as possible, for the color once lost can never be regained. The best results are obtained when less than ten or fifteen minutes elapse between the time that the tissue is removed and its submersion in the fixing fluid. If several hours must intervene, dry cloths or cotton should completely envelop it to absorb the moisture. Refrigeration, while preserving the color temporarily, should not be employed on specimens to be thus prepared. All free blood adherent to the surfaces, due to the surgical or post-mortem operation, should be gently washed away, and the tissue placed in a relatively large amount of the following solution:

No. 1: Potassium nitrate.. 15 grams
Potassium acetate.. 30 grams
Formalin ..... 200 cubic centimeters
Water .....1,000 cubic centimeters

At this time care must be taken to have the various parts placed exactly as they are finally to remain, for within a short time they become fixed in whatever position they happen to be, and cannot be altered thereafter. If the specimen possesses a cavity, as does the gall-bladder, appendix, intestine, etc., the contents may be carefully removed and replaced by some of the above solution. A very successful way to preserve the natural contour of the unopened gall-bladder is to introduce the fluid through the cystic duct with an injecting syringe, its subsequent escape being prevented by a ligature or an artery forceps. A large, firm organ, such as the liver, should be sectioned before immersion, in order to allow the solution to penetrate equally every part and give uniform results. In the case of the lungs, the trachea and bronchi may be utilized as channels through which the liquid may be forced to every minute part. Metals should not be used here, or at any other stage of the process, to force light tissues to sink. We have found that in these cases the specimens, if allowed to float after lightly wrapping in a considerable amount of gauze, will be satisfactorily preserved. The length of time essential for complete fixation of color varies with the size and variety of specimen. About twelve hours will usually prove sufficient for the majority. Brains, blood clots, and very large specimens require from one to two days. At the end of this time the object, which should now be comparatively firm, is removed from the liquid, immersed for a few minutes in water, and then placed in

No. 2: Alcohol.

From the color standpoint, this is the most important part of the entire process, as the return of the color temporarily lost in No. 1 solution will be partial or complete, according as the alcohol is applied for an improper or a proper length of time. And the only way to determine that proper time is to watch each individual case. When the tissue is removed from the fixative fluid, the blood is of a dark-brown color. Upon submersion in alcohol this is gradually replaced by a light-red one, essentially the same as normal blood. As soon as this tint is seen the alcohol may be known to have acted sufficiently long, and should be removed at once. From one to five hours will probably be a fair average for the majority of preparations. Prolonged immersion will cause the color to fade, after which it cannot be regained. Others have recommended two alcohols of varying strength, but if the amount of fluid in proportion to the size of the specimen be large, a single solution will give practically as good results. Occasionally, the selected surface will not look very fresh, even after the use of alcohol, probably on account of overfixation. This may often be remedied by cutting a thin slice from the edge, thus exposing an area on which the fluids have not acted so intensely. In fact, it is our custom, in preparing kidneys, livers, and similar specimens, to preserve intact that part through which the section is to be made until after the alcohol has acted for a few minutes. By this means a freshness is secured that is not otherwise attainable.

Fig. 2.

The colors having now returned, whatever excess of alcohol is present is washed away by water, or the specimen may be placed without washing into

No. 3: Potassium acetate.. 100 grams
Glycerin ..... 200 cubic centimeters
Water ..... 1,000 cubic centimeters

Here it may remain for days or months as a permanent mount (Kaiserling), or it may be continued to the final step. The sooner this last step is taken, however, the better will be the preservation, as No. 3 tends to macerate tissue. Some of our best specimens have been subjected to this solution for less than one hour.

No. 4: Gelatin ..... 200 grams
Solution No. 3 ... 3,000 cubic centimeters

As great care is required in the preparation of this last mixture, its technique will be described in full before commenting upon the mounting of the specimen. For some time we recommended soaking the gelatin in No. 3 for one or two days, but have later obtained better results by combining the two and immediately heating. About three or four liters are placed in a good agate-ware pail, which is placed directly over a gas stove, the entire solution being brought to the boiling point in the shortest possible time. Care must be taken to prevent burning, although the danger is not great. When a temperature of about 55° C. has been reached, and the gelatin is nearly all melted, the white of one egg is added for every liter present, and the entire solution is rendered strongly acid by acetic acid. The coagulated white of egg helps to clarify, as does also the acetic acid. In addition, the acid probably renders the medium a better color conserver. As soon as boiling becomes active, the hot preparation is poured into a filter with two thicknesses of paper, and the clear solution is collected in the stock jar. When ribbed funnels are used no difficulty is experienced in the process, but with the smooth ones more rapid results are attained by placing the whole apparatus into a large steam sterilizer, where the gelatin will not solidify. After solidification, a crystal of thymol placed on the top of the stock solution will effectually prevent the appearance of fungi.

In a container holding about two liters there should be but little more color to the solution than there is to pure water. In smaller amounts there should be practically no color at all. Having now prepared our medium we will proceed to the permanent mounting. This may be performed in square museum jars, round jars, test tubes, etc., according to the nature of the specimen, but will be probably more attractive and useful if made in a Petri dish,

as described in our article of 1902, to which reference has already been made. The thymol is now removed from the stock solution of gelatin and the bottle is placed in a steam sterilizer for liquefaction. When completely liquid, and at a temperature of about 45° or 50° C., a thin layer is poured into a Petri dish, and to it is added about one drop of formalin to each 20 c.c. of the solution. Into this is placed the specimen, face downwards, where it is allowed to stay till the gelatin has become solid. More of the formalin-gelatin solution is now added, sufficient to almost, but not quite fill the dish. This should be allowed to solidify thoroughly for ten or twelve hours in the ordinary room temperature. More of the same preparation is finally added, till a slight convexity is formed above the edge. A wet plate glass is now quickly placed on the liquid gelatin in such a way as to force out all the air bubbles and rest evenly upon the upper edge of the dish. This may be performed in one of two ways. The plate may be allowed to touch first one side of the dish and then gently lowered in such a manner as to form a wave of gelatin that will drive out all bubbles. (Fig. 2.) Or it may be pushed on from one side, the plate and dish being parallel, if an excess of the solution be maintained in front of the advancing edge. (Fig. 3.) This being completed, it is set aside for an hour or more, with the plate still on top. The superfluous gelatin is now gently removed with a coarse brush, and a cement of Canada balsam, with 20 per cent. clove oil, is applied around the entire circumference. The next day the glass is carefully washed, another coat of balsam is applied, and the specimen is permanently mounted.

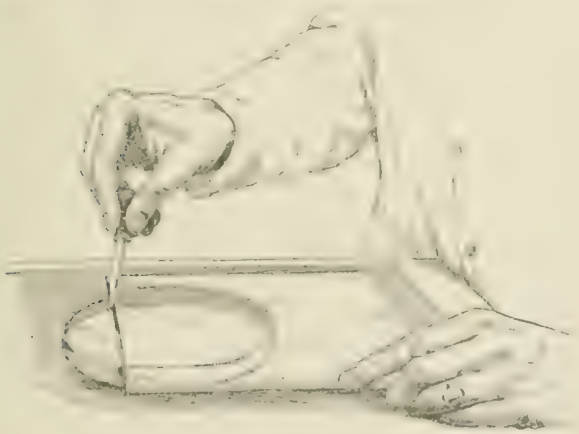

Fig. 3.

Petri dish-mounting is more complicated and requires much more practice than do the jar mounts, but, as stated above, is much more attractive.

Great care must be taken in using the formalin. Too much will cause undue contraction of the gelatin and appearance of air bubbles; too little will allow liquefaction with its resultant disadvantages. Just enough will (and has) preserved the specimen in practically perfect condition for years. Another point to be noted is the complete solidification of the full dish of gelatin before applying the cover. This allows of about all the contraction that will naturally occur, thus tending to prevent the entrance of air bubbles. The Petri dishes are the same as ordinarily used in bacteriological work, and may be obtained in various dimensions. With the smaller ones common window glass may be used as bases, but for the larger ones plate glass will be preferable. If the side away from the specimen be ground it provides a good background and brings the specimen into greater prominence. Its only objection is that it obscures one face of the object, which usually is not of great importance. The shape of this plate is optional, some preferring it to be square, others giving preference to the rectangle. Canada balsam, even with the addition of clove oil, is not a perfect sealing agent; it is, however, so much more pleasing in appearance than the various gutta percha compounds that it is preferred. A fresh, thin coat, quickly applied with a camel's-hair brush every six to twelve months, will usually be successful.

For labels, we use white zinc to number the specimen (Abbott's classification) and ordinary white ink for the name and diagnosis. The former is permanent, the latter easily removed with the moist finger—a very convenient thing when quizzing a student. Others attach typewritten cards to the glass with balsam, which is often an excellent method.

Much simpler than the above is the mounting of specimens in jars and large test tubes. Here all that is required is to fill the container with a sufficient amount of formalin-gelatin, place therein the specimen, allow to solidify, and put on the top. In the majority of these cases a small air space is left at the top of the jar. Various parts of plants have been mounted in this No. 4 solution after fixation in a single formalin solution, with good results. The same statement will apply to preservation of flies, leeches, fish, snails, cockroaches, and many of the other lower forms of life.

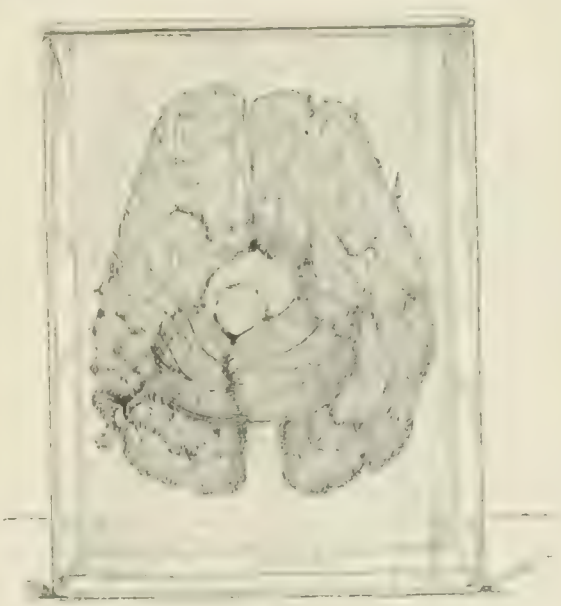

Fig. 4.

At the recent meetings of the American and the British Medical Associations, the effect of direct sunlight and heat upon these mounts was well shown. In both places many specimens were purposely placed in the place of greatest exposure. The balsam in one case became soft, allowing the Petri dish to slide off, but except for this, not one showed any effect, and in none did any air bubbles appear. Extreme cold may at times cause so much contraction as to crack the glass. This is not common, much less so within the past two years than in the earlier ones when we were less accustomed to the method.

In our first article four advantages were claimed. Let us see if these claims have been proven true.

1. The permanency of the mounts. There are now in our museum mounted specimens that have made all the following return journeys: Saratoga, N. Y.,

1902; Cleveland, O., 1902; St. Louis, Mo., 1903 (six months exposed to light at the Exposition); Portland, Ore., 1904 (six months same as at St. Louis); three Boston exhibits apart from the University buildings. Four hundred specimens were packed by ordinary workmen and shipped by freight from Oregon, with breakage of less than ten. Surely these facts should be conclusive.

2. The compactness and neatness. This assertion to those who have seen the preparations needs no further explanation.

3. The easy adaptability for class demonstration. Interest with understanding has increased much in those classes where these preparations have been used. In addition to their use as hand specimens, we use them in our reflectoscope, thereby throwing upon the screen a reflection of the real object in its natural colors, more satisfactory than any picture.

4. The successful preservation of color. Specimens first mounted nearly six years ago, which have been almost continually in the light, show no appreciable loss of color.

Much credit for useful suggestions and assistance in working out the practical details must be given to my assistants, Drs. F. S. Morris, now of Pittsburg, and C. A. Eaton, of Boston. Grateful recognition is also given to others working with the same method in other laboratories, since our first publication. Many valuable ideas have thus been obtained from Prof. W. M. L. Coplin of Jefferson, Dr. Henry Albert of Iowa, Dr. Wolbach of Harvard, and Prof. Leary of Tufts, for which the writer expresses his sincere appreciation.

THE TREATMENT OF LA GRIPPE.*

By CHARLES E. NAMMACK, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

THERE is neither a prophylactic nor a specific for influenza. It is obviously impossible to formulate a specific plan of treatment for an acute infectious disease, occurring in widely-extended epidemics, characterized by catarrhal inflammation of the mucous membrane of the entire respiratory tract, and less frequently of the digestive tract, and attended by quickly oncoming debility, and by nervous symptoms. Not only is the disease exceedingly variable and protean in its manifestations, but we must differentiate, in the individual instance, between a case occurring during a pandemic invasion, as an endemic incident, as an epidemic occurrence, or as a sporadic outbreak. In the first instance, the element of panic enters largely into the calculation. In the second, the environment must be considered. In the third the prevailing type of the epidemic must be estimated. In the fourth we must carefully differentiate the ordinary catarrhal respiratory inflammation, which has an obvious exciting cause—usually changeability of the weather, lacks the characteristic depression, does not attack many members of the same family, and has, as a rule, a lower range of temperature and less involvement of the nervous system. I will say nothing here about the necessity for excluding acute miliary tuberculosis, typhoid fever, malaria, or one of the ordinary infectious eruptive fevers.

Having decided that we have to deal with a case of general influenza due to Pfeiffer's bacillus, or probably to the residual germs which remain after a pandemic invasion, our first duty is to endeavor to prevent the spread of the disease. To this end, we should isolate the patient, even though we cannot reasonably hope, by this measure, to diminish either the activity of the infecting principle or the susceptibility of other individuals. The nasal and bronchial discharges should be disinfected with the same careful attention to detail that is shown in other acute infectious diseases. The patient himself should be at once put to bed, for, although prophylaxis against the attack is theoretical and to a great extent impracticable, prophylaxis against sequels is in the highest degree practical and useful. Those who continue at work and endure exposure not infrequently suffer at a later period of the disease from the most serious results. A fair-sized, single dose of calomel, followed if necessary by a saline draught, will help to eliminate some of the infection, if given at the time of the initial chill. The patient's bed should be warmed, and he should receive, in the bed, a footbath of hot mustard water with rubbing of the extremities, and a hot drink. Alcohol will be useful in those accustomed to its use, also in the aged, and in the weak. Young, healthy, abstemious patients will not need it at this stage. The diet should be restricted to milk, albumen water, gruel, and the ordinary fever foods. The use of milk should not be pushed in those who have a heavily-coated tongue, for it will only cause indigestion. Concentrated meat broths can be used, unless active diarrhea or the condition of the kidneys should be a contraindication. Acidulated drinks will relieve the thirst in some, and also soothe the stomach, and flush the kidneys. Others will be benefited by alkaline fluids, such as vichy, or by bland waters. Cold baths and cold compresses are generally not well borne, and increase the discomfort.

The average patient will expect to swallow drugs, and the atrocious pains sometimes present will suggest the use of analgesic antipyretics. It is my personal conviction that drugs of this class contributed more to the death rate during 1889-1890 than did Pfeiffer's bacillus. At the present time their use is not so general, but they still occupy too prominent a place in the lay mind. Pain which is severe enough to require drugging will be better managed by Dover's powder or codeine. Another drug largely used by self-prescribers in this affection is quinine. There is not the slightest evidence that quinine in any dose favorably modifies the course of the attack, or shortens its duration, although it may be useful during convalescence. The old rule that "the physician is to be a watchman all the time and a therapeutist only when occasion arises" applies with striking force to influenza, yet the symptoms of this affection cry aloud for relief, and of these symptoms the depression and the respiratory catarrh will in most cases be prominent. I usually meet these symptomatic indications by a prescription containing five grains of ammonium carbonate, five grains of ammonium salicylate, and half an ounce of the aromatic wine of erythroxylon coca (of the National Formulary) in each dose. This may seem like active therapy, but this combination has done me yeoman service during many years in private practice, and in

*Read before the Eastern Medical Society of the City of New York, November 9, 1906.

dispensary and hospital services. It will relieve headache and neuralgia and stimulate the heart, respiration, and kidneys. Incidentally, I may remark that it is sometimes fearfully and wonderfully made by apothecaries who are pressed for time. When this combination fails to meet the indications mentioned, the case is serious enough to require constant attention, and the hypodermic use of strychnine, caffeine, or camphor. The stage of convalescence must be carefully managed by tonic and supporting treatment, especially addressed to the nervous system, in order to avoid the formidable array of complications and sequels, any of which may develop even in mild cases.

The most common complication is bronchitis. This will require its usual treatment, with the important reservation that no remedy should be employed which is a sedative to the nervous or circulatory system. This reservation excludes antimony, aconite, veratrum viride, potassium salts, and large doses of ipecac, and compels us to fall back upon steam inhalations, hot drinks, counterirritation, rest in bed, and codeine for excessive cough. Should bronchopneumonia develop, strychnine and aromatic spirits of ammonia, well diluted with water, are indicated. Oxygen inhalations, though much derided, are advantageous in some cases. The presence of profuse bronchial secretion in the smaller tubes positively contraindicates morphine.

The poison of influenza is capable of setting up serious changes in the intracardiac ganglia and in the myocardium; therefore, the pulse and the heart sounds must be carefully studied, and all unnecessary movements on the part of the patient absolutely prohibited until the rhythm and force of the heart have been restored. The three tinctures, nux vomica, belladonna, and digitalis, act well in bringing about this result, or a similar combination of strophanthus, cactus grandiflora, and belladonna, sometimes acts efficiently. The coexistence of valvular disease of the heart will add its own specific indication for treatment.

Kidney impairment will also supply a field for therapeutic intervention, which is too wide to be gone over within the limits of this paper. Symptoms referable to the nervous system may dominate the clinical picture from the onset, or may become prominent at any time during its course. It is no uncommon sequel to see robust, self-reliant men converted into feeble hypochondriacal valetudinarians by an attack of grip, which has weakened the general nervous mechanism, as well as the special nervous apparatus of the heart. This sequence of events seems especially liable to happen to scholars and brain workers, who should receive the benefit of a long period of rest with entire change of scene and employment before taking up again their life work.

The tragic results of the formation of a drug habit during this period should make us extremely cautious in inaugurating the use of hypnotics, sedatives or analgesics. Headache, insomnia, neuralgia, neurasthenia, hysteria, chorea, peripheral neuritic disturbances, and psychic disorders, may all seem to the patient to demand drugs, but the practitioner who relies upon outdoor life, freedom from worry and care, moderate exercise within reasonable limits, good nerve-building diet, and hydrotherapy, will leave in his wake the more grateful memories. In the stubborn neuralgias during the period of convalescence, quinine, in moderate doses, is more effective than its modern coal-tar competitors, and is frequently useful where they have failed.

42 East Twenty-ninth Street.

THE VALUE OF THE DIFFERENTIAL LEUCOCYTE COUNT IN GYNECOLOGY AND ABDOMINAL SURGERY.*

By FREDERIC E. SONDERN, M.D.,

NEW YORK.

It is a gratifying fact that since the publication of my first paper concerning the value of the differential leucocyte count in diagnosis and the added significance this gives to the leucocytosis, read before the Surgical Section of the Academy nearly two years ago, the matter has at least by some been given the attention I believe it deserves, with very happy results. Further evolution of this diagnostic aid has led to no change in the fundamental principles concerned as follows:

The increase in the relative number of polynuclear cells is an indication of the severity of the toxic absorption, and the degree of leucocytosis an evidence of the body resistance toward this absorption. It is evident from the above that neither the differential leucocyte count alone nor the actual leucocyte count alone is of any value, and if diagnostic data is to be had from the examination of the blood, it must be obtained from a consideration of these combined factors. Within reasonable limits the figures obtained justify an inference as to the probable presence or absence of a purulent exudate. Purulent exudates are rarely if ever present with low polynuclear percentages, irrespective of the height of the leucocyte count, while very high polynuclear percentages almost invariably indicate their presence even if the leucocyte count is low. My continued daily contact with cases in which this diagnostic aid is sought strengthens rather than weakens my belief in this valuable adjunct in surgical diagnosis, presenting as it does, diagnostic and prognostic data at a time when the clinical picture may be confusing.

Since that time a number of criticisms have appeared which would tend to prove this diagnostic help of doubtful value, and it is unfortunate that such statements are usually made without proper regard to the fundamental principles on which the method is based, and enumerate a series of pitfalls without any mention of the much larger number of happy results. It is so self-evident as to scarcely merit mention, that a blood examination can no more take the place of bedside observations than a urine analysis can indicate the presence of a diabetic coma without the bedside confirmation; still this is an argument frequently used against a purpose never intended by the most ardent advocates of the method. Figures have been quoted of cases where purulent exudates have been found without a relative polynuclear increase in the blood, with evident disregard of the fact that the pus was enclosed in such a way that no toxic absorption occurred which explains the blood picture. Other groups of cases are mentioned in which high polynuclear percentages were unaccompanied by purulent exudate or gangrene, not mindful of the fact that such polynuclear increase may also be seen in other than suppurative conditions. As in every other technical procedure, these different counts, in order to be at all accurate, demand a certain amount of technique and faithful execution, frequently ascribed to the hospital interne, undeservedly in many instances, as I know from personal experience.

While it is true that pitfalls and errors surround this as all other diagnostic methods, and it is of use only to the discriminating clinician who learns to

*Read at the meeting of the Obstetrical Section, New York Academy of Medicine, November 22, 1906.

apply it, still nobody can gainsay the fact that it fills a place occupied by nothing else. A few examples may be quoted to emphasize this point.

Take a case of severe pneumonia, with high leucocytosis and pronounced relative polynuclear increase. A fall in the leucocyte count with an increase in the polynuclear percentage is a sign of impending danger, and often precedes the clinical signs of this danger by twelve to twenty-four hours.

A case of appendicitis, with possible gangrene, or a case of otitis media, with possible mastoid involvement, may present a complex of symptoms which possibly are coupled with conditions somewhat opposing operation, so that the surgeon is really in doubt as to the absolute necessity of interference. The differential count, together with the leucocyte count, particularly if repeated, has been the direct cause of saving many of these cases by immediate operation of which I have record. In none of the examples quoted has the blood examination given any aid in the direct diagnosis, nor has it detracted one iota from the necessity for careful bedside observation, and still it is impossible to deny that it has been of great value to the clinician. Concerning the practical application of the method, I can use no more fitting words than by quoting from Dr. C. L. Gibson's paper in the *Annals of Surgery* of April of this year. The higher the polynuclear percentage as compared to the leucocyte count, the greater the probability of a purulent exudate. It is of value chiefly in indicating fairly consistently the existence of suppuration or gangrene, as evidenced by an increase of the polynuclear cells disproportionately high as compared to the total leucocytosis. The greater the disproportion the surer are the findings, and in extreme disproportions the method has proved itself practically infallible. As the relative disproportion between the leucocytosis and the percentage of polynuclear cells is of so much more value than the findings based on a leucocyte count alone, this latter method should be abandoned in favor of the newer and more reliable procedure.

Dr. Gibson has also advocated the use of a standard chart which I heartily indorse; by means of it the important factor of the relation between polynuclear increase and leucocyte increase is graphically demonstrated.

Concerning the direct diagnostic and prognostic aids obtained in the different classes of cases from the use of this method, it was essential for me to tabulate in my earlier papers such cases in which I could obtain the necessary clinical data. This is obviously a difficult matter for the laboratory worker, and as it has been done by clinical authorities and we are to have the pleasure of hearing from Dr. C. L. Gibson and Dr. H. C. Taylor in the discussion this evening, I will not pursue this branch of the subject. I should like, however, to refer to Dr. Gibson's paper just quoted, as well as to a paper by Dr. Taylor read before the New York Obstetrical Society in February of this year.

Dr. J. F. McKernon has given this method of examination a careful trial in suppurative conditions associated with or following middle ear disease, and is also enthusiastic on this adjunct in diagnosis. He intends voicing his opinion and results at a meeting of the Surgical Section of the Academy in December. In a general way I may add that suppurative bone processes do not give us figures as high as we generally see in suppurative conditions in the soft tissues, probably on account of slower toxic absorption.

With my enthusiasm in advocating this diagnostic help in acute inflammatory lesions and differential diagnosis, I grant you that the procedure is still crude, and that many refinements are necessary in order to make it as useful as we would like, but this is only a question of research.

In closing, I should like to add a few words concerning the disappointments and failures encountered in the application of the method. Children, particularly infants, do not give the uniform results obtained in adults. It must be recalled that in these the normal polynuclear percentage is a more variable quantity, and when they are severely infected it seems that a drop in the polynuclear percentage may be due to a lack of ability to further absorb toxic material, thus indicating a graver rather than an improved condition. When pus is confined in such a way that no toxic absorption occurs, or when a purulent exudate is the result of a tuberculous or typhoid infection alone, there is no leucocytosis and no polynuclear increase. Experience also teaches that a mixed infection with or following tubercle bacilli or typhoid bacilli, does not show the high polynuclear percentages obtained in primary staphylococcus or streptococcus infection.

It is also found that the exact nature of the infection has a direct bearing on the degree of polynuclear increase, some organisms causing higher percentages than others, everything else being equal. A very small percentage of cases of error remains unexplained by the above, and in these one must conclude that we are led astray by drawing inferences from a specimen which does not happen to be a proper indicator of the circulating blood, even if the technique is as good as understood.

From my experience with the method I feel firmly convinced that it has gained a place as a diagnostic aid, that it merits every effort in the direction of improvement, and that the disappointments encountered should stimulate such effort rather than tend to condemn the procedure.

THE PSYCHIATRIC CLINIC AT MUNICH, WITH NOTES ON SOME CLINICAL PSYCHOLOGICAL METHODS.*

By G. H. KIRBY, M.D.,

PATHOLOGICAL INSTITUTE, WARD'S ISLAND, NEW YORK

The psychiatric clinic at Munich is probably attracting to-day more students of psychiatry than any other institution in Europe. One meets indeed a cosmopolitan assemblage in the laboratories and lecture rooms, among which a goodly number of Americans are to be found. In the building of the clinic many of Professor Kraepelin's ideas and suggestions were carried out, and certainly its admirable construction and complete equipment as well as the usual facilities for teaching and investigation give to the Munich clinic a unique and foremost position. A location was chosen in close proximity to the other medical buildings of the university, which are found not far from the center of the city, yet an agreeable distance from the noisy business districts. The city of Munich has about half a million inhabitants and the clinic was designed to accommodate one hundred patients—the annual number of admissions is about 1,200. The building itself consists of a central part with two wings, in the latter of which the wards are located. The central division of the building contains the administrative offices, an out-patient department, the psychological laboratory, a large auditorium, library, and histological laboratory.

* Read before the New York Neurological Society, October 2, 1906.

In the wards the dormitory system prevails almost entirely, and exclusive of the division for private patients there are only two single rooms in the whole clinic in which patients can be placed; these are, however, never used for purposes of isolation. The dormitories contain from ten to twelve beds each, and upon visiting the wards one is struck by the prevailing quietness and good conduct of the patients. One hardly believes that he is in the reception wards for acute cases. The foreign students, that is some of the Americans, were inclined to attribute this good order to perhaps some characteristic of the German race; Professor Kraepelin, however, ascribes it entirely to the methods of treatment in vogue, especially to rest in bed, the dormitory plan for observation, and the continuous baths, and also to the fact that most of the patients enter the hospital without going through the hands of the police and the trying circumstances of arrest and perhaps detention in prison. Both admission and discharge of the patients from the clinic is made as easy as possible; many come voluntarily to the hospital, and more are brought by friends; a legal process for detention is resorted to only when necessary.

The Kraepelinian school has been criticised for a lack of interest in treatment. Indeed one quickly observes that drugs are rarely prescribed and then only to meet definite physical conditions; on the other hand hydrotherapy is carried out in the clinic probably more extensively than in any other institution in the world. Tubs suitable for the continuous bath have been liberally provided, there being no less than eighteen available for this purpose. There appears to be no contraindication to the continuous bath; all forms of excitements and agitations are favorably influenced—manic attacks, delirious alcoholics, anxiety psychoses, and excited general paralytics are treated by this method. No drug sedatives or restraint of any kind are used.

As regards the organization of the clinical work, mention can be made of only a few points. There are about twelve physicians on the staff and the principle of rotation on the services obtains. Besides looking after his service, each physician carries on some fairly definite line of investigation. Each man has every year a period of three months during which he is relieved from the care of his service in order that he may take up some special problem or finish some work already started. The records are still written in long hand, and this, of course, makes them to a certain extent inaccessible to the foreigners. The anamneses and observation notes are probably less full than the records which we are at present making in our New York State hospitals. The clinical material met with in Munich differs in several respects from the ordinary run of cases as seen, for instance, at the Manhattan State Hospital—dementia præcox, manic-depressive insanity, general paralysis, alcoholic and hysterical psychoses, with a large number of epileptics, form the bulk of the diagnoses; the delirious forms and the infective-exhaustive psychoses so frequent in the material coming from our American cities are remarkably scanty. The involution melancholias are extremely rare. During the past year considerable interest has been aroused in the clinic through the finding of several cases presenting the syndrome described by Adolf Meyer in 1901 in connection with his work on "Central Neuritis." The anatomical findings as well as the clinical picture correspond to Meyer's description.* Kraepelin inclines to the view that one deals here with a disease entity and proposes the name of anxiety psychosis, disregarding the fact that this name has already been applied by Wernicke to an altogether different symptom-complex.*

One of the assistant physicians is doing special work on the pupillary reactions; he has constructed an apparatus which is probably an improvement on Bumke's. The pupils are viewed through a small telescope, definite amounts of light can be thrown in either eye and the alteration in size of the pupils accurately measured in millimeters. The behavior of the pupil can also be easily observed under emotional stimuli and painful cutaneous impressions. The reaction to which I wish to call special attention has been designated the "secondary light reaction," and is described as follows:

Illumination of, say the right pupil, with a definite amount of light causes, as would be expected, a contraction of the left pupil as well as the right (ordinary consensual reaction). If now the left pupil is illuminated with the same strength of light as the right, then the left pupil contracts still further, and likewise the right pupil, and in a sufficient degree to be measured. In other words, a definite amount of light thrown into one eye causes both pupils to contract equally, and then a further equal contraction of both pupils occurs when the other pupil is subjected to the same amount of light. This constitutes the secondary light reaction. The failure of this reaction was not observed in any healthy individual nor in any of the psychoses examined, except general paralysis. A series of general paralytics was examined in whom the ordinary light reaction was still present.

In 96 per cent. of these cases the secondary light reaction was absent. The investigator thinks that this sign is of importance because in a series of over 500 general paralytics examined in the ordinary way, 18 per cent. of the pupils reacted normally and in another 40 per cent. a reaction to light was still present. The so-called psychic and sensory pupillary reactions are being studied in dementia præcox, epilepsy, and hysteria.

I wish to refer briefly to some of the recent work in lumbar puncture. The use of platinum needles is recommended. In addition to the cover slip preparations obtained in the usual way from the centrifuged specimen the number of cells is also estimated per cubic millimeter by means of a specially constructed Zeiss counting chamber similar to that used in ordinary blood work, except that the chamber is deeper and the ruled surface larger.

In order to make this estimation, ten parts of fresh cerebrospinal fluid are mixed with one part of a staining fluid in an ardinary blood counting pipette, and from this the counting chamber is filled. The staining fluid consists of methyl violet and acetic acid. Above six to nine cells per cubic millimeter is considered abnormal. In counting, the results are tabulated as: Polynuclears, large lymphocytes, and small lymphocytes. Fischer of Prag recently read before the German Psychiatrical Society, which met in Munich, a paper on the anatomical basis of the cell findings in the cerebrospinal fluid of general paralysis. He compared the findings in the fluid drawn shortly before death with the findings in the meninges of the brain and cord in twenty cases examined post mortem. In the study of the cellular elements of the spinal fluid he used a method which it is claimed allows a satisfactory differential cell count. To the freshly drawn fluid some formalin

*Meyer, Adolf: On Parenchymatous Systemic Degenerations, mainly in the Central Nervous System. *Brain*, 1901.

*Wernicke: Grundriss der Psychiatrie: Angstpsychose, p. 227.

is added in order to at once fix the cells. The specimen is then centrifuged and cover slip preparations made and stained in the customary way. One finds then usually three types of cells, viz., lymphocytes, large plasma cells and polynuclear leucocytes. Fischer found an agreement to exist between the cellular contents of the fluid and the infiltration of the membranes covering the lower parts of the cord, while this agreement did not exist between the fluid and the condition of the membranes of the brain and upper parts of the cord; that is to say, an infiltration of the meninges of the brain and upper cord alone did not yield a positive cell count. Further, he observed that when a lymphocytosis predominated in the fluid, a lymphocytic infiltration of the membranes could also be demonstrated. If the spinal fluid was rich in plasma cells then this type of cell predominated in the pia. He concluded that the cytological elements indicated nothing more than the state of infiltration of the meninges of the lowest cord sediments.

Alzheimer in discussing this paper said that his experience did not lead him to believe that the cells in the spinal fluid originated from the neighboring membranes. He had found in brain abscess an increase in the polynuclear leucocytes in the spinal fluid without any corresponding increase of the same elements in the meninges of the cord. He also knew cases in which a lymphocytosis was found in the fluid during life, but in which the diagnosis was arteriosclerosis and not general paralysis. These were old syphilitic cases and post mortem he did not find any increase in the lymphocytic elements of the spinal meninges.

To Kraepelin is due the credit of having established the first laboratory where the methods of experimental psychology could be applied to the study of insanity. The organization of the psychological laboratory in the Heidelberg Clinic in 1890 opened a hitherto neglected field of investigation. Following Kraepelin's lead similar laboratories have been established in connection with several other psychiatric clinics.

On the question as to what psychiatry can expect to get from the psychological laboratory, Kraepelin takes, I think, a healthy attitude. Laboratory methods certainly offer no easy road for the solving of the problems of psychiatry and can never replace accurate clinical observation, but if we can learn in the laboratory how to better understand some symptoms, or if we are able to analyze certain mechanisms more satisfactorily, then the method has proved its usefulness. The great amount of time and the equipment required in this line of work practically precludes its being done except under special conditions, yet there are some methods in use which can be applied easily and quickly enough to be practicable in any hospital for the insane. I wish to refer to a few of these.

As a measure of the amount of mental work which an individual is capable of doing, Kraepelin and his pupils have developed and extensively applied the so-called method of continuous addition.* Sheets with single rows of figures are placed before the patient, who adds each two figures together and the number of additions accomplished in every minute is indicated by a stroke of the pencil which the patient makes as each minute is called off by the physician. The experiment lasts ten days, the patient works ten minutes daily, adding as many figures together as possible in that time. On alternate days a pause of five minutes follows the first five minutes of work, then after this rest another five minutes' work is done. With this method we have a simple, yet probably the best way of estimating fatigue and at the same time we are able to determine the influence of practice and the restorative action of a pause during the work. Curves can be easily plotted to show the results. Because of the strong complaints of fatigue made by patients suffering from a traumatic neurosis Specht* examined a series of these cases. Increased fatiguability was indeed found to be present, but because the patients failed to show improvement with practice Specht thought he had discovered a means of uncovering dissimulation and malingering. A recent investigation, however, of Plaut, in the Munich Clinic, seems to show that other factors may account for the absence of improvement with practise. In the further application of this method a variety of psychoses demand study, especially the psychasthenics, hysterias, the affective melancholias, alcoholics and perhaps the group of dementia præcox.

For the study of apprehension and retention a fairly simple apparatus is used. By means of a shutter arrangement a number of letters, usually six, are exposed to the eye of the patient for a known length of time. In this way is determined the number of letters correctly perceived and the length of time they are retained in consciousness. By this method it is possible to study the delay in apprehension and the memory disorder of the alcoholics, especially the Korsakoff delirium.

Another means which Kraepelin has used in the analysis of certain symptoms, especially motor phenomena, is furnished by the "writing-balance." With this apparatus one can measure the rapidity with which the patient writes as well as the pressure of the pencil on the paper, duration of pauses, and the size of the letters.

As one of the most important aids which we have at hand to-day in the analysis of certain mental conditions must be mentioned the "association tests." As this work has recently been thoroughly reviewed in the Psychological Bulletin,† I will refer here to only some of the interesting results obtained by Aschaffenburg and Jung.

Aschaffenburg studied the types of associations obtained in states of fatigue, in alcoholism and mania with especial reference to the reaction time and the occurrence of sound associations. On the ground of these experiments he based his belief that flight of ideas was a phenomenon secondary to the motor disorder. Jung has used the association tests for a different purpose, and has led the way into one of the most promising fields in which we are to-day working. He has shown how we can by this method discover undercurrents of thought or uncover hidden complexes existing in the patient's stream of mental activity. He has been working especially with hysteria and dementia præcox. By a recent clever psychophysical experiment he has been able to show in another way the existence of these complexes. During the association experiment a weak galvanic current is allowed to pass through the patient's head. Now when a sensitive spot or a submerged complex is touched upon by one of the words given for association, not only is the reaction time prolonged, but a corresponding alteration occurs in the electric current.

PRURITUS ANI.*

By T. CHITTENDEN HILL, M.D.,

BOSTON.

SURGEON TO THE RECTAL DEPARTMENT OF THE BOSTON DISPENSARY.

THE writings and teachings of our most eminent dermatologists as well as proctologists would lead one to infer that the annoying symptom known as pruritus ani might be caused by any one of an enormous number of distinct diseased conditions, both local and constitutional, and the various plans of treatment advocated are so numerous that the whole subject, to the general practitioner at least, is enshrouded with a great deal of mystery. To the writer it would seem especially fitting, because of the more satisfactory methods of treatment that have been originated largely by members of this society, that an attempt should be made to classify more definitely the common causes, and outline what we consider the more approved methods of treatment.

The habit of attributing aggravated cases of pruritus to constitutional diseases, such as diabetes, rheumatism, gout, tuberculosis, and syphilis, or to such gross lesions as internal hemorrhoids, anal fissure, fistulæ, prolapsus recti, etc., should be regarded in the light of our present knowledge as antiquated theories. Pruritus ani is the symptom caused by an unnatural moisture or discharge produced either by lesions about the anus, or by congestion or some pathologic condition in the rectum or sigmoid. This constant and irritating secretion, even though slight and scarcely discernible, eventually brings about pathognomonic changes of a mildly inflammatory nature in the structure of the epidermis of this region, which result in the typical chronic and subchronic dermatitis of the rectal pruritic.

The purpose of these remarks is to mention under five divisions my own views as to the cause of pruritus ani, in order if possible to get the sentiment of this Society upon the subject.

1.—First, and by far the most important causes of pruritus ani, are superficial ulcerations or abrasions of the anal canal. This lesion is very constant, and should always be sought for. Mr. F. C. Wallis of London first called attention to the frequency with which it occurred in pruritus. He maintains that it is present in 90 per cent. of all cases, and attributes the frequency of its occurrence to the method of fusion of the proctodeum with the blind end of the gut. He says: "The fusion takes place at a variable line between the sphincters. The lining membrane of the proctodeum is thin, and, unlike the mucous membrane, is scantily supplied with blood-vessels, and thus abrasions in this locality are easily brought about. But, because of the ever-altering condition of the sphincters, and because of the contents of the bowel, they rarely heal of their own accord." His method of treatment, briefly described, is as follows: The ulcer is cocainized by the injection of a few drops of the solution immediately beneath it. This elevates the lesion so that it can the more readily be cauterized with the galvano-cautery knife. After this it is smeared with vaseline, and an opium suppository is inserted in the rectum. In very bad cases, when there is considerable ulceration, Mr. Wallis is in the habit of using a general anesthetic in order that the sphincters may be stretched and the actual cautery used.

Three years ago I had an opportunity of seeing Mr. Wallis treat a large number of patients* by this method, and was greatly surprised that the cure of such a small lesion as was sometimes discovered would so quickly relieve the patient of the intense itching. Since then, in my own practice, I have often demonstrated the fact that the whole cause of the pruritus may be attributed to a very small ulcer or abrasion of the mucous membrane of the anal canal.

2.—Catarrhal Diseases.—The rectum in such instances is never entirely free from feces, a condition which is productive of chronic forms of proctitis, sigmoiditis, superficial ulcerations, etc. The passage of flatus at such times allows a small quantity of mucus to escape, thus irritating and rendering moist the anal region. These patients are best treated by securing soft evacuations of the bowels at least once in every twenty-four hours, by means of a suitable aperient taken at bed-time. After the bowels have moved in the morning they should be washed out with a half pint of a 4 per cent. boric acid solution. Furthermore, it will be found beneficial to make stimulating applications of silver nitrate or balsam of Peru to any abrasions or ulcerations which may remain. This is best effected with the proctoscope, with the patient in the knee chest position.

3.—External hemorrhoids are more frequently the cause of pruritus than internal ones. These ragged tags of redundant skin render it almost impossible for the patient to cleanse properly the anal region after defecation. This persistent fecal soiling sooner or later produces a dermatitis in persons predisposed to its occurrence. This variety of hemorrhoid may easily be removed after injecting with a one-quarter or one per cent. solution of eucaine. The wound may be allowed to heal by granulation, yet, if the base of the hemorrhoid was broad it is better to close it with catgut sutures. When the folds are numerous only two or three should be removed at one time, lest anal contraction take place.

4.—Situated from 3-9 mm. above Hilton's white line are several small pockets, the functions of which, so far as the writer is aware, have never been satisfactorily explained. It is asserted that they have something to do with either the secreting or the storing of rectal mucus, while, on the other hand, Stroud suggests "that they are simply the mechanical result of constricting the wide rectal tube to its small rectal orifice." The free borders or valves of these small pockets consist chiefly of nerve fibers, ganglion cells, and a very small amount of connective tissue elements. These little pockets will admit a probe which has been bent upon itself from one-quarter to one-half an inch, and with the windowed anoscope may be readily seen and explored. The thought had frequently occurred to the writer that these little crypts with their valves, when inflamed or infected, might be the cause of a reflex nervous disturbance manifested by a pruritus of the perianal skin. Keeping this idea in mind, I have in two instances, which resisted other treatment, succeeded in quickly allaying the itching by swabbing out these little pockets with a 1 per cent. solution of nitrate of silver, or a 15 per cent. solution of ichthyol in glycerin. While not wishing to convey the impression that any considerable number of cases of pruritus are due to disturbance of this portion of the anal canal, yet I am of the opinion that if a routine anoscopic examination of the crypts was made upon cases whose etiology was obscure, this condition

*Read before the American Proctologic Society, Boston, Mass., June 6, 1906.

*These patients were treated at St. Mark's Hospital for Diseases of the Rectum, London.

would occasionally be observed. In the two cases of this kind which I have treated the patients seemed to get very little relief from local applications, but by inserting the finger in the rectum relief and sleep were best obtained. Therefore I would suggest this as a symptom of irritation in this locality.

Growing from the margins or surfaces of these valves one frequently finds little white projections or *teats,* which can be made out by the exploring finger. Stroud explains their presence here as "accessory sense organs of a higher degree of development than the major part of the pecten, and not pathological outgrowths." When hypertrophied or elongated they cause many distressing sensations about the anus. Among them may be mentioned uneasiness in the rectum, such as a "creeping, crawling" sensation, and a feeling of incomplete relief after defecation. Quite frequently pruritus is the most prominent symptom. The treatment of these cases by ablation is very satisfactory. It consists in snipping the growths off with a pair of anal scissors as they protrude through the window of the anoscope. It is best to apply a strong solution of cocaine before removing them.

5.—Small polyps of the anal canal, protruding internal piles, prolapse of the rectum, and anal fissures, as well as other conditions, do doubtless occasionally cause itching about the anus, but very seldom in the writer's experience are they the cause of an old chronic or inveterate pruritus ani. When encountered, however, associated with pruritus they should be dealt with according to their special surgical indications.

Now, notwithstanding the fact that the exciting cause has been discovered and eliminated, it is necessary to direct appropriate treatment to the unnatural skin before much amelioration of the itching can be expected. It seems probable that it is the product of a chronic inflammation of the skin, with more or less thickening and infiltration, which in some way throws out of gear the "simple nerve endings which exist so abundantly in the epidermis." It is this departure from the normal which produces the sensation of itching; therefore it is our task to make such applications as will restore the skin to normal. The patient should be instructed to cleanse thoroughly the anal region after defecation, preferably with absorbent cotton which has been wrung dry of some antiseptic solution. The parts should be protected from friction and the irritation of the discharge by wearing day and night an anal pad held in place by a T-bandage. The pad is best made with absorbent cotton wrapped with but one thickness of sterilized gauze. Too many thicknesses of gauze, when ointments are used, absorb the greasy portion of the ointment, and shortly the anal region becomes dry and coated, with only its irritating mineral ingredients. The methods of applying and removing ointments are such important matters that in the first few weeks of treatment they should be seen daily by the surgeon. Simply to instruct the patient to use some of the ointment morning and night will inevitably result in failure.

Those cases in which the dermatitis is acute (eczema ani), accompanied by many excoriations from scratching and rubbing, require applications and ointments of a soothing and protective nature. However, in the class of patients who are here especially referred to, the skin is nearly always tough and leathery and covered with dead and sodden epithelium. The problem in these cases is to bring about a gradual destruction of this new formed epidermis, without too much inconvenience to the patient, and I know of no agents that serve the purpose better than nitrate of silver and citrine ointment (ung. hydrag. nit.), applied as suggested by our worthy President, Dr. Adler.*

It has been my experience that in those cases in which the skin was considerably thickened and tough, the saturated solution of silver is the more satisfactory. On the third day after its application, by placing hot fomentations over the anus for a few moments, a layer of exfoliated epithelium may be removed almost in toto.

In those cases, however, in which the skin was more delicate the same purpose is served equally well with the weaker solution.

For this class I have found an ointment composed as follows, more suitable than the citrine: red oxide of mercury three drams, Venice turpentine one ounce, lanolin three ounces.

*Dr. Adler's method: At the first visit the perianal skin is painted with a saturated solution of nitrate of silver. Provided any abrasions present are previously anesthetized with a 10 per cent. solution of cocaine this should occasion no discomfort. The application of the silver should be repeated at intervals of four or five days until all the dead epithelium has been removed. After the silver has dried the anal region is smeared with citrine ointment. The patient is seen daily for the first two weeks and then every other day for a like period. After this, once or twice a week until the skin has regained its original color, suppleness, and elasticity.

Anatomico-Clinical Forms of Congenital Malformations of the Heart.—After speaking of infantile cyanosis due to cardiac malformation, Jules Sebilleau says that besides this classic malady there exist several varieties of congenital cardiac malformations which can be diagnosed during the life of the patient. Among these he discusses the persistence of the ductus arteriosus. Normally this structure is transformed a few days after birth into a fibrous cord. In certain cases, however, it persists; this persistence may constitute the only congenital lesion. During life the diagnosis is based on the following signs: the existence of a systolic murmur behind the lung to the left of the vertebral column between the spinous processes and the spinal border of the scapula, at the level of the third and fourth dorsal vertebræ; distinct inspiratory reinforcement of this murmur; a marked influence on the arterial pulse of the two periods of respiration, the pulse being weaker during inspiration and stronger during expiration; complete absence of cyanosis which is explained by the passage into the ductus arteriosus of blood which comes from the aorta; red blood from the aorta mixes with dark blood from the pulmonary artery and cyanosis cannot occur.—*Gazette Médicale de Nantes.*

Deep Injections of Alcohol at the Point of Emergence of the Facial Nerve in Cases of Blepharospasm.—Valude has been using deep injections of alcohol as a therapeutic measure in cases of blepharospasm. This operation consists in injecting one and one-half cubic centimeters of 80 per cent. alcohol, together with .01 gr. of cocaine. The needle is inserted at a point between the anterior surface of the mastoid process and the inferior surface of the external auditory meatus. It is so directed that it glides behind the styloid process. In this way the point of emergence of the facial nerve is reached. Gentleness should be used in making the injection. At first .20 gr. is injected, and after a few moments the rest is injected in smaller quantities. In the two cases of blepharospasm in which Valude has used this treatment the pain of operation was very slight. At first a complete facial paralysis developed on the side in which the injection had been made. This paralysis rapidly cleared up. The palpebral spasm has not reappeared. In case of its recurrence it would be easy to make a new injection.—*Revue Française de Médecine et de Chirurgie.*

MEDICAL RECORD.

New York, December 22, 1906.

THE TRYPSIN TREATMENT OF CANCER.

THE reports which have appeared recently in the MEDICAL RECORD on the result of the injection of pancreatic ferments in the treatment of cancer are exceedingly interesting, even if not conclusive. They are certainly of such a nature as to demand further essays of the remedy, though the lessons of the past should not be forgotten, and while trypsin is still on its trial it will be salutary to remember that there have been other remedies which seemed to promise well at first, but which are now, figuratively speaking, collecting dust on the top shelves of the pharmacies, out of sight and out of mind. The weak points in the case of trypsin, so far as it has been presented, are three: the small number of cases, the short time that has elapsed since the reported cures have taken place, and the lack of anatomical confirmation in most instances of the diagnosis of malignancy.

In some of the cases the diagnosis was established by a microscopical examination, and in others, such as the interesting laryngeal case reported by Dr. Rice, the clinical evidence of malignancy would have been accepted as conclusive had the disease run its usual course. But clinical evidence is insufficient in dealing with what is, according to all past experience, so improbable a fact as the absolute cure of cancer. Even a microscopical diagnosis in isolated cases would be brushed aside by the sceptical, if not by the judicial, as possibly erroneous, and the objectors will not be silenced until this diagnosis has been made a number of times by a number of competent microscopists.

The diagnosis being accepted, the number of cases in which the growth has disappeared after the use of trypsin and the other pancreatic preparations must be many times what they now are before the medical world will admit that a cure for malignant disease has been discovered. The instances of spontaneous cure of cancer are not few, and the disease has been seen to disappear under many and various forms of treatment. Violet leaves, condurango, thyroid extract, and even soap have been reported as effective in a number of cases, and it is possible they may have given the fillip needed by Nature to enable her to work a cure. Trypsin may act in the same way, or it may be endowed with a specific curative action. The cases thus far reported are too few to warrant a definite opinion.

Time alone can determine the actuality of the reported cures. Recurrence is the rule in all cancer therapy, whether by the knife, the *x*-ray, Coley's fluid, or other remedies, and few, even among those who are convinced that the cases treated were malignant and that the growths have disappeared under trypsin injections, will maintain that there is no possibility of recurrence. Yet, that is what we should expect if the theory of Prof. Beard, upon which the present experiments are based, is true. It is his belief that if the left-over asexual cells, which are the cancer cells, are once destroyed by trypsin, any further cancerous growth is impossible. The theory, with all its corollaries, is entitled to respectful consideration in view of the reports, meager though they still are, of apparently successful results, but time alone will prove it.

It may be noted, though the fact is not of much weight, that the reports of the results of the trypsin treatment in England have thus far been uniformly unfavorable. The remedy has been tried at the Cancer Hospital, the Middlesex Hospital, and other institutions in London without success, and Mr. Edmund Owen, in a recent lecture on cancer, asserts that there is no known method of treatment of cancer "which can honestly and confidently promise a cure." In explanation of this failure it is contended that the pancreatic extract used was inert, and that it was not administered properly. We have seen no detailed reports of these experiments and so are not in position to judge of their value, but if the trial of this method of treatment in America should eventually prove its worth, it would not be the first instance of a prophet finding honor in a country other than his own. The results of the trypsin treatment of cancer in this country are not yet sufficient to carry conviction and further trials may result in another disappointment and lead to the abandonment of the method, but we believe such trials are fully justified by the apparent success already obtained.

THE FUNCTIONS OF THE OMENTUM.

ALTHOUGH it is generally assumed that the omentum plays an important rôle in the physiology of the abdominal cavity, we find but few satisfactory presentations of the subject. Numerous references are scattered throughout the literature, and many of these have been collected by G. K. Dickinson in the effort to arrive at some conclusions of value (*Annals of Surgery*, November, 1906). The various functions of the omentum are determined by the different tissues which go to make up its substance, and, as the organ is closely connected with others in the abdominal cavity, the study of its functions involves the study of all. Taking up first the question of the circulation, it is quite evident that the large blood supply of the omentum makes it an important factor in maintaining an equilibrium in the abdominal circulation. For the relief of arterial tension, it is important that some part of the circulatory apparatus be capable of storing up blood. This the intraabdominal vessels are ready to do, and chief among them those of the omentum. This organ is also capable of equalizing the circulation in another manner, by becoming adherent to some area of local inflammation, and in this way affording a collateral circulation sufficient to relieve a localized venous tension. Another important function is attained through the vascular system in conjunction with the lymphatics, for as its extensive

surface is continually exposed to surrounding parts plenty of opportunity is given for absorption of fluids by the blood stream.

The adhesive property of the omentum is one peculiar to itself, and is well known. When irritated by some regional inflammation an exudate appears on its surface, which subsequently leads to an attachment and encapsulation of the offending area. The majority of the phagocytes extruded into the peritoneum for its protection have been shown to come through the omentum, and it has also been demonstrated that lack of development in the omentum, or loss through operation, renders the patient less resistant to peritoneal infection. Finally, it has been found that if the circulation of the spleen is entirely cut off the omentum gradually encapsulates the organ, and in time complete absorption of the latter occurs. Warthin believes that there are hemolymph glands of the splenic type existing in the base of the omentum, which may become enlarged and even functionate for the spleen if the latter is removed or its functions are interfered with. All of these collected facts show that in the omentum we possess a structure which is associated with a multitude of functions beyond that of mere protection to the abdominal viscera.

SCHOOL BATHING.

The establishment of a sufficient number of public baths in New York City is a matter of slow progress and the slipshod manner in which some of them are managed, in comparison with the efficient conduct of those under the charge of the Association for Improving the Condition of the Poor, is not calculated to increase enthusiasm over their further extension. We undoubtedly have much to learn from Continental countries in this respect. The working classes of Germany and France certainly keep themselves cleaner than do those in England and America. More recently the effort has been made on the Continent to supply the schools with baths and thus develop in very young children a practical knowledge of the pleasures of cleanliness.

An interesting report on this matter was not long ago presented to the London County Council by Dr. Kerr and Mr. Rose, who officially visited thirty-five schools in twelve cities of Germany and Holland—namely, Wiesbaden, Mannheim, Frankfort, Karlsruhe, Munich, Nuremberg, Halle, Berlin, Hanover, Cologne, Düsseldorf, and Amsterdam. "In all these, as generally throughout the countries visited, baths are provided in every school and every child, with the exception sometimes of the very young, bathes once a week. The precise arrangements differ, but as a rule the children stand in tanks of warm water to soap themselves and then have the soap washed off by a warm shower bath, gradually cooled as it is continued. There is a plentiful supply of towels and the bathing is controlled by a sufficient number of careful attendants. It is manifestly so conducted as to be pleasant to the children and to give them a constantly recurring experience of the comfort attendant upon a clean skin, so that it can hardly fail to lay the foundations of a habit likely to be enduring."

The problems of modern life are increasing here in this town with bewildering rapidity and complexity. We are all becoming more and more crowded and personal cleanliness is becoming more and more a necessity. We cannot make men good by mere legislation, but we can make it easier for them to be clean. If our Board of Education would take some steps in the direction indicated above, no one would call its members "fad-chasers." The enmity to soap and water is confined to an infinitesimal portion of the population. Unfortunately the average tenement offers few facilities for comfortable bathing. They are generally limited to the family washtub, which for various purposes does almost daily duty. No wonder then that the average child in such surroundings regards the bath as a penance instead of a pleasure. If we can inculcate a love of cleanliness in his mind and demonstrate that its attainment may be made a matter of actual pleasure we shall have gone far toward a solution of one of the perplexing problems of modern life in large cities.

THE FREQUENCY OF GONORRHEA AND ITS EFFECTS.

Of the lessons of modern medicine few have been deemed more important or have been emphasized with greater stress than the doctrine of the widespread prevalence of gonorrheal diseases among men, and consequently of the grave menace to the health of married women that this condition entails. While there is absolutely no reason to doubt the general correctness of this teaching or to question the wisdom of disseminating as widely as possible among the laity a knowledge of the perils that attend promiscuous sexual intercourse, there is a possibility that the numerical estimates of some of those who have interested themselves in the matter have been rather exaggerated. This at least is the opinion of Erb, who has of late years occupied himself very largely with the collection of statistics in regard to the prevalence of both gonorrhea and syphilis.

In a recent publication (*Münchener medizinische Wochenschrift,* November 27, 1906), he attacks particularly the results obtained by means such as those employed by Blaschko, whose horrifying figures have been quoted with great frequency and made the basis of sweeping generalizations that, according to Erb, are not justified by the facts. Blaschko, out of 10,000 male inhabitants of Berlin, found that eighty-three were suffering from gonorrhea in a single day, and by a series of multiplications which Erb considers unjustifiable reached the conclusion that every unmarried man, after five years of celibacy, contracts gonorrhea once, and after ten years twice. Furthermore, that every fifth young man after eight or ten years becomes syphilitic. Consequently, he says, every man who marries after the age of thirty years has had gonorrhea twice, and every fourth or fifth bridegroom is syphilitic. It is impossible to reproduce in detail Erb's arguments against the method of reasoning or to give all of his own statistics, which are much less pessimistic in tone. He contends that the only way to obtain reliable figures is not to begin with the young men and calculate what is likely to happen to them in the future, but to take the older individu-

als and find out what actually has happened to them in the past. The results obtained by investigating the past histories of 2,000 of his private patients lead him to the conclusion that only every other man has ever had gonorrhea, and that almost half of the male population has been entirely free from venereal disease of any sort. While these figures, though tragic enough, are much less alarming than those of Blaschko, the result of Erb's inquiries into the frequency of gonorrheal lesions among married women is still more encouraging. He found that among the wives of his gonorrheal patients only 6.25 per cent. had ever presented any symptoms that could be referred to gonorrheal infection, and that instead of "one child sterility" being the rule in these cases, as is often alleged, in 370 marriages in which the husband had had gonorrhea, 68 per cent. had had at the time of examination two or more children, and 25 per cent. had had four or more.

These figures of Erb's are certainly interesting, and though this method of investigation is by no means above criticism from several obvious standpoints, they probably may be taken as an indication that in their laudable zeal the alarmists have gone a little further than necessary. Still, even taking Erb's figures as correct, the showing is a terrible one and holds out a sufficient probability of punishment in store for the waywardness of youth. It is to be hoped that others who have access to a large clinical material in other countries will conduct similar inquiries, and especially is it desirable that other classes of society be investigated, for Erb's patients were almost entirely members of what he terms the cultured middle class.

Facial Erysipelas in a Mother the Cause of a Purulent Peritonitis in the Child.

Erysipelas, as generally observed in the newly born, occurs especially during the first few weeks of life. Although it may follow a wound or abrasion of the skin, it most often originates at the umbilicus. It then is frequently complicated by other lesions such as peritonitis and umbilical phlebitis. In instances when it originates in other parts of the body it may be uncomplicated. The tendency of erysipelas in the newly born is to spread with rapidity. The usual symptoms are well known, being great prostration, localized pain, and tenderness, restlessness, wasting, vomiting, and diarrhea. The prognosis is grave. L.-M. Bonnet in the *Lyon Médical* of November 25, 1906, reports a most unusual and interesting case of peritonitis in a boy about ten weeks old, whose mother had an attack of facial erysipelas. From birth up to the time of his death the child gained rapidly and regularly in weight. He appeared to be vigorous. He was born on July 19. About the end of August he became very subject to diarrhea. This condition ceased with treatment, but returned quickly when treatment was stopped. In spite of the recurring diarrhea his general condition remained excellent. It was while he was in apparently perfect health that the illness which caused his death developed. On September 30 the diarrhea increased and vomiting took place. The child was restless and was evidently ill. The abdomen was slightly distended. On the following day the patient was much worse and in the afternoon he died. Autopsy disclosed a purulent peritonitis. In its course and in its symptoms the peritonitis, in this instance of erysipelatous origin, resembled peritonitis due to puerperal infection. The whole course of events in this case appeared to take place inversely to the ordinary course of these phenomena. Erysipelas of the newly born is due most generally to a maternal septicemia, but in this case the mother who was attacked by erysipelas was the source of a subacute peritonitis in her child. The only case that the writer has been able to discover in the literature which at all resembles the one he reports was a patient of Meunier's. She was a girl sixteen years old and fell ill of erysipelatous peritonitis after nursing her mistress who was suffering from facial erysipelas.

Some Recent Observations on the Complement.

It has long been known that certain of the bactericidal sera were less potent for the protection of infected animals in large doses than they were when employed in comparatively moderate quantities. Apparently inexplicable, at first, this phenomenon was ingeniously elucidated by Neisser and Wechsberg in their work on the absorption of the complement, or thermolabile element of these sera, by the excess of immune bodies or amboceptors. The process, termed by them "Komplement-Ablenkung," or deviation of the complement, important in itself, has led to other observations of even greater practical value. One of the greatest of these is the recent discovery that the complement can be diverted from its amboceptor and rendered *hors de combat* by substances not at all participating in the immunizing or lytic reaction (as the case may be). Ehrlich and Sachs, Bang and Forsman had previously shown this to be possible for substances like yeast and extracts of red blood cells. Landsteiner and his associates, however, have made a distinct advance by proving within recent months that the complement of hemolytic sera may be absorbed by colloid and suspended substances normally present in the human body. Protagon, cholesterin, serum-albumin, peptone, and glycogen are among these, and the ease these observers seem to have experienced in finding substances which possess this inactivating affinity for complement renders it more than likely that there are a host of others, among the many and complex components of the tissues, which may act similarly toward the complements of many hemolytic and immune sera. The importance of this work lies chiefly in the explanation it offers for the failures of attempts at immunization by the ordinary methods in the case of many of the infectious diseases, and the hope it holds out of the overcoming of the difficulty by the concentration of the complement.

The Ocular Manifestations of Hereditary Syphilis.

An interesting and important contribution to the pathology of the various ocular lesions that are so frequently associated with hereditary syphilis is contained in observations made by Bab (*Deutsche medizinische Wochenschrift*, November 29, 1906), on the eyes of three syphilitic stillborn fetuses. Spirochetes have already been studied in the cornea by several investigators, notably Bertarelli, and Greef and Clausen, but these observations were the result of the artificial inoculation of the rabbit's eye, and therefore especial interest attaches to Bab's researches as being the first successfully carried out on actual clinical material. His preparations were made by means of the Levaditi modification of the silver impregnation method, and he deprecates

the view that to secure good results it is necessary to employ only very small bits of tissue. Instead of this he adopted the plan of placing the entire eyeball in the silver solution, and then searching through every portion of the organ by the very laborious method of making serial sections. In each case spirochetes were found in large numbers and could be demonstrated in practically all of the ocular tissues except the lens and the vitreous body. It is the author's opinion that the spirochetes through the blood stream are brought in large numbers to the eye, and then lodge in the tissues, multiply, and wander on into the neighboring structures. In accordance with the distribution of the vascular system of the eye they are found most abundantly in the choroid, from which they pass on into the substance of the iris, and into the sclerotic and deeper layers of the cornea. These facts seem to the author to explain satisfactorily the mode of formation of syphilitic keratitis, choroiditis, and iritis, while the demonstration in one case of spirochetes in the optic nerve, the retina, and also in the external ocular muscles throws light on the pathology of specific neuroretinitis, optic atrophy, and external ophthalmoplegia. Bab also discusses the allegations of those who claim that the "silver spirochetes" are only artefacts composed either of nerve fibrils or of portions of degenerated cells containing nerve terminations. He disposes of the first objection by stating that his preparations show the spirochetes in the middle of the lumen of blood-vessels, and of the second by stating that the cellular preservation in his specimens was perfect, and that all details of structure were most clearly defined. Like most investigators in this field, he believes that the spirochetes bear an etiological relationship to syphilis, and considers that the fact that they could not be found in the bodies of any of the nonsyphilitic infants also studied in the same way as controls argues against the possibility of their existing simply as chance parasites.

Separation of the Normally Inserted Placenta in the Course of Pregnancy.

This subject has for years excited the interest of obstetricians, and various opinions have been advanced regarding it. Jules Gaston, in the *Annales de Gynécologie et d'Obstétrique,* of November, 1906, gives a detailed résumé of this question. Many years ago Mauriceau reported in a treatise a certain number of observations of retroplacental hemorrhages. Following the appearance of this article were others by Peu, 1694, and Leroux, 1776. But it is J.-L. Baudelocque who handles this question with especial frankness in his treatise on the art of delivery. Some years afterward Mme. Boivin and Mme. Lachapelle, however, denied the existence of this affection. Later writers, since the observations of Winter, have made contributions to the study of placental separation. Among these observers are Tarnier, Mme. Henry, Pinard, Varnier, Ribemont-Dessaignes, and Champetier de Ribes. Gaston opens his discussion with a consideration of the etiology and pathogenesis. Under the first heading he considers anatomicopathological causes and ordinary clinical causes. Under the symptomatology he discusses the general condition, abdominal pains, the condition of the uterus, and accessory signs. An interesting section deals with statistics. That on pathological anatomy including reports on postmortem examination is of great interest. Gaston refers to the theory of Schickelé, who thinks that the placental separation may take place in such a manner that small effusions of blood on the interior of the decidua form progressively, so that coagulation follows and with it arrest of hemorrhage. He believes that the hematomata act like a solid foreign body in bringing about pain and consequently uterine contractions. Gaston believes that in cases in which the patient is suddenly attacked by intense pain in the abdomen with all the signs of severe internal hemorrhage the uterus has not had time to react. He thinks that the separation precedes all of the phenomena of contraction.

A Plastic Operation to Replace the Thumb.

The functions of the thumb are so important that it is usually considered that the loss of this member is equivalent to the loss of half the hand. The desirability of endeavoring to provide a suitable substitute in cases in which the thumb has been amputated either accidentally or by the surgeon is evident and an ingenious method has been proposed by Nicoladoni. This surgeon some years ago reported a plastic operation he had performed on a child in which he used the second toe to replace the thumb. The same idea has been applied by Krause (*Berliner klinische Wochenschrift,* November 26, 1906), who was consulted by a young clerk whose thumb had been amputated in childhood by a chopping machine. The deformity was so hampering to him in his work that he was willing to undergo any discomfort for the sake of securing a substitute for the missing member. Krause accordingly resolved to attempt to transplant the patient's great toe. The stump of the thumb contained a portion of the proximal phalanx and this was denuded of the old cutaneous scar. An incision was then made over the interphalangeal joint of the toe, and the skin, extensor tendon, and upper surface of the joint were divided. A short section of the proximal phalanx was excised and the stump of the thumb was inserted into the cavity so formed, the skin and extensor tendons of the two parts being united by sutures. The arm was then affixed to the leg by a massive plaster-of-Paris dressing in such a way as to secure complete immobility. It is stated that, although the cramped position required the use of opium during the first few days, the patient's discomforts after this were not severe. On the seventeenth day the exarticulation of the last joint of the toe was completed and the flexor tendon was sutured to that of the thumb. The wound healed without complications, and according to Krause's description the new thumb presents a very good appearance. Tactile sensation has developed over a portion of the grafted member, and although there is as yet but little or no power of voluntary motion of the transplanted phalanx, the operator is hopeful that under appropriate exercises this will be acquired. Even as it is, he says, the patient can use the hand for most of its ordinary functions.

Public Lecture at the New York Academy of Medicine.—The first public lecture of the winter will be delivered in Hosack Hall, in the Academy of Medicine, 17 West Forty-third street, on Saturday evening, December 29. The lecturer will be Dr. Wilfred T. Grenfell, C.M.G., physician to the missions of the Labrador Coast, who will take for his subject, "The Work of a Labrador Doctor." The lecture will be illustrated by lantern slides. Dr. Grenfell's work in the scattered Labrador settlements is of a unique character, and his account of the same promises to be of unusual interest. The lecture is open to the profession and the public.

News of the Week.

American Association for the Advancement of Science.—The annual meeting of the American Association for the Advancement of Science will be held at Columbia University From December 27 to January 2. The President of the association for the New York meeting will be Dr. W.H. Welch of Johns Hopkins University. J. J. Stevenson is the Chairman and Prof. J. McKeen Cattell the Secretary of the local Committee of Arrangements. The program of Section K, Physiology and Experimental Medicine, includes an address by Dr. William T. Sedgewick on "The Expansion of Physiology," and a symposium on the protozoa as factors in disease in which the following speakers will take part: Prof. E. B. Wilson, Prof. Gary N. Calkins, Dr. C. W. Stiles, Prof. F. G. Novy, Prof. James Ewing. The first session will be the business session, and will be held at Schermerhorn Hall, Columbia University, December 27, at 11 A. M. The second session, at which the protozoa will be discussed, will be held at the College of Physicians and Surgeons, December 27, at 2.15 P. M. The third and fourth sessions will be held at the Rockefeller Institute for Medical Research, on December 28 and 29, at 10 A. M., and will be joint sessions with the American Bacteriological and American Physiological Societies respectively. The Chairman of Section K is Dr. Simon Flexner, and the Secretary is Dr. William J. Gies.

The "Philippine Journal of Science."—Owing to the increase in the amount of material to be published, this journal will in future be issued in three divisions, devoted respectively to general science, medical sciences, and botany. The section on general science will include articles on chemistry, geology, and mineralogy, zoölogy (including entomology and ornithology), and a series on ethnological and ethnographical subjects. The section on medicine will be devoted to tropical medicine, studies in bacteriology, pathology, immunity, and work on serum production and therapy. The section on botany will include all botanical work issued from the Bureau of Science.

The Nobel Prize Awards.—As announced in a recent issue of the MEDICAL RECORD, the Nobel Prize in Medicine was divided between Prof. Golgi of the Pavia University and Prof. Ramon y Cajal of Madrid. Prof. Moissan of Paris received the chemistry prize for his experiments in the isolation of fluorine and his researches into its nature, also for his application of the electric furnace to scientific uses. Prof. Thomson of Cambridge University received the physics prize for his researches into the nature of electricity. The King of Sweden formally presented the prizes and medals on December 10.

The Yerkes Hospital.—The late Charles T. Yerkes provided in his will for a large hospital to be built in this city, but the carrying out of the plan has been delayed by litigation over several million dollars' worth of Chicago traction securities. It has now been decided in the federal court in Chicago that these securities rightfully belong to the estate, so that the erection of the hospital is assured. The counsel to the trustees states, however, that there are still a number of matters to be settled, the adjustment of which will require considerable time, before which work on the buildings can be begun.

A Perfect Method of Water Analysis.—In his message on the Panama Canal, sent to Congress on Monday of this week, President Roosevelt, speaking of the water supply of Colon and its purity, says, "I drank it and it was excellent." There is evidently no occasion for chemical and bacteriological tests after such a careful analysis, and any allusion to the *Bacillus coli* would be entirely out of order.

The Pope's Physician.—The position of pontifical physician left vacant by the death of Dr. Lapponi was first offered by the Pope to Prof. Di Venezia, who was his physician when he was Patriarch of Venice, but owing to his advanced age the physician declined the appointment. The post was then conferred upon Dr. Petacci of Rome. The salary paid to Dr. Lapponi was $1,200. It is said that applications for appointment to this honorable post were received by post and telegraph from nearly every country in Europe and America.

To Investigate the Pennsylvania State Hospitals.—A commission has been appointed by Governor Pennypacker to investigate the management of the institutions for the insane in Pennsylvania. The commission began its labors at the State Hospital at Harrisburg on December 17, and has subpœnaed great numbers of witnesses, including doctors, nurses, and officials.

Unlicensed Sanatoriums to Be Prosecuted.—The State Lunacy Commission has announced its intention of investigating and if necessary prosecuting two sanatoriums in New York and Brooklyn said to be receiving insane patients without being licensed to do so. The attention of the authorities has been directed to these institutions through the suicide recently of two of their inmates. It is expected that the entire matter of the conduction of private sanatoria in this city will be made the subject of an inquiry by the commission.

The Chicago Health Department recently sent its estimate for next year to the City Comptroller. Commissioner Whalen is asking for $788,840, as against $461,845 for this year. One hundred inspectors are requested for work in the public schools to prevent the spread of contagious diseases. There are sixteen men in the department so engaged at this time. New inspectors will be paid $75,000 if the appropriation is carried. The department wants $25,000 for public baths in the Twenty-fourth Ward, and $43,000 to take over the ambulance service from the police.

Need for Another State Institution.—In the opinion of the committees of the State Board of Charities conditions in this State demand the construction in Eastern New York, at a point preferably in the vicinity of New York City, of a State institution to be devoted to the custodial care of the senile and feeble minded and epileptics who are not proper subjects for the overcrowded institutions already maintained by the State for that class. At a conference between the State Board of Charities and the heads of the present institutions it was ascertained that there were 481 inmates of the Craig colony at Sonyea who should be cared for at such a new institution, and that there were 200 such inmates in the institution at Syracuse for the feeble minded, 200 in the Newark State Institution, and 200 in the Rome Custodial Asylum. In addition there are at least 600 inmates of almshouses throughout the State who need such custodial care, and it was stated that the work of all of these institutions was greatly hampered by the overcrowding due to the presence of patients of this class.

Woman's Hospital.—The vacancy in the Medical Board of the Woman's Hospital, New York, occasioned by the resignation, several years ago, of Dr. Thomas Addis Emmet, has been filled by the nomination and election, December 10, by the Board

of Governors, of Dr. J. Riddle Goffe, to the position of visiting surgeon. The new hospital was opened for the reception of patients December 6.

Craig Colony for Epileptics.—According to the thirteenth annual report of the Craig Colony for Epileptics just issued the present census is nearly 1,300 all told; when the new buildings are completed the total census will be approximately 1,500. The subject states that the new hydrotherapeutic plant recently installed has been found very valuable in the treatment of certain types of epilepsy. The net per capita cost of keeping each patient at the Colony last year was $141.38.

The Spread of Glanders in England.—The increasing use of automobiles in London is said to be responsible for the dissemination of glanders among horses all over the Kingdom. Formerly glanders was rare outside of London, but since horse traffic in the metropolis has been largely and increasingly replaced by motor omnibuses and motor cars, the disease has been scattered through the county by the sale there of London's abandoned horses.

Ambulance Accident.—A Kings County Hospital ambulance in charge of Dr. Albert and carrying a patient to the hospital was run into last Friday by a trolley car. Dr. Albert, the driver, and the patient were all thrown to the street, and the former received a fracture of the skull and internal injuries. The driver's left arm and right leg were broken and his head cut open, but the patient escaped further injury.

A Serum for Cerebrospinal Meningitis.—The press despatches state that Dr. Kolle, Professor of Bacteriology in the University of Berne, Switzerland, has announced that he has been able to produce a curative serum for use in cases of cerebrospinal meningitis.

Wishes Divorce at 105 Years.—It is reported that an application for divorce was filed on December 14, in a Kansas court, by a woman aged 105 years. The cause given is extreme cruelty, and the plaintiff alleges that since 1898 she has been unable to live with her husband, who is fifteen years her junior, on this account.

Dr. Thomas Addis Emmet of this city has been made a Knight of St. Gregory by Pope Pius X., in recognition of his devotion to his profession and his services to the Catholic Church.

Dr. D'Orsay Hecht has been appointed attending neurologist to St. Elizabeth's Hospital, Chicago.

Southern Medical College Association.—This association held its annual meeting at Baltimore, Maryland, December 10, 1906, under the presidency of Dr. Christopher Tompkins of Richmond, Virginia. All of the medical colleges belonging to the association were represented except the Fort Worth Medical College and the Medical College of Alabama. The resignation of the University College of Medicine at Richmond, Virginia, was presented and accepted. The following colleges were elected to membership: Medical Department of Southwestern University, Dallas, Texas; Medical Department of the University of Georgia, Augusta; Medical Department of Epworth University, Oklahoma City, Oklahoma. The following applications for membership were filed, to be acted on a year hence: College of Physicians and Surgeons, Atlanta; Mississippi Medical College, Meridian, Mississippi, and the Medical Department of the University of Arkansas, Little Rock. An amendment to the constitution looking to the making of the minimum preliminary educational requirement, a high school diploma, or its equivalent, was carried over until the next meeting. The President, in his address, advocated more rigid preliminary educational requirements. Hereafter the association will meet in connection with the Southern Medical Association in October of each year. Dr. Christopher Tompkins was reelected President; Dr. G. C. Savage of Nashville was reelected Treasurer and Secretary, and Dr. James B. Bullitt, Jr., of Oxford, Miss., First Vice-President.

American Laryngological, Rhinological, and Otological Society.—The annual meeting of the Eastern Section of this society will be held at Providence, Rhode Island, January 5, 1907. The Chairman is Dr. Frank B. Sprague, 27 Stewart street, Providence, Rhode Island.

Claiborne County (Miss.) Medical Association.—At its annual meeting, recently held, this organization elected the following officers: *President,* Dr. J. F. McCaleb; *Vice-President,* Dr. E. D. Barron; *Secretary,* Dr. George W. Acker.

Orleans Parish Medical Society.—The newly-elected officers of this society are: *President,* Dr. John J. Archinard; *First Vice-President,* Dr. John B. Elliott, Jr.; *Second Vice-President,* Dr. C. J. Landfried; *Third Vice-President,* Dr. John Laurans; *Secretary,* Dr. Amedee Granger (reelected); *Treasurer,* Dr. E. O. Tranan.

Graften County (N. H.) Medical Society.—The following officers have been elected by this society to serve for the ensuing year: *President,* Dr. F. Von Tobel, Lebanon; *Vice-President,* Dr. G. W. McGregor, Littleton; *Secretary* and *Treasurer,* Dr. G. A. Weaver, Warren.

Gregg County (Texas) Medical Association.—This society elected the following as officers at its recent meeting, held in Longview: *President,* Dr. H. M. Lawrence; *Vice-President,* Dr. M. B. Feemster; *Secretary and Treasurer,* Dr. E. E. Terry.

Jackson County (Mich.) Medical Society.—Officers were elected as follows at the annual meeting of this society, held at Jackson, on December 6: *President,* Dr. Martha C. Strong; *Vice-President,* Dr. F. W. Rogers; *Secretary,* Dr. T. A. Longford; *Treasurer,* Dr. E. A. Martindale.

Lauderdale County (Miss.) Medical Society.—At a meeting held December 7 officers for this society were elected as follows: *President,* Dr. H. F. Tatum; *Vice-President,* Dr. W. J. Anderson; *Secretary-Treasurer,* Dr. J. Bennett.

Massachusetts Surgical and Gynecological Society.—The thirtieth annual meeting of this organization was held at Boston on December 12, and the following were elected as officers: *President,* Dr. Frank A. Gardner of Salem; *Vice-Presidents,* Dr. Amanda C. Bray of Worcester and Dr. A. Howard Powers of Boston; *General Secretary,* Dr. Frederick W. Colburn of Boston; *Associate Secretary,* Dr. Herbert D. Boyd of Boston; *Treasurer,* Dr. Isabel G. Webster of Wellesley.

Macon (Ga.) Medical Society.—At the recent meeting of this society the following officers were elected: *President,* Dr. James T. Ross; *Vice-President,* Dr. G. P. Gostin; *Secretary,* Dr. J. C. McAfee; *Treasurer,* Dr. R. B. Barron.

Portland (Me.) Medical Club.—The election of officers, held at the recent annual meeting of this society, resulted as follows: *President,* Dr. C. R. Burr; *First Vice-President,* Dr. E. G. Abbott; *Second Vice-President,* Dr. F. Y. Gilbert; *Secretary-Treasurer,* Dr. W. W. Robinson.

Obituary Notes.—Dr. William W. Purssell of Whitehouse Station, N. J., died on December 8. He

was a graduate of the Normal Institute at Carversville and received his medical education at Jefferson Medical College in Philadelphia. He had practised in Whitehouse for thirty-two years, and was well known throughout Hunterdon County.

Dr. Alfred Wilde Gardner of this city died on December 10 of sepsis following an infection received while performing an operation. Dr. Gardner was graduated from the College of Physicians and Surgeons in 1890 and during the summers was resident physician at Sharon Springs.

Dr. William James Herdman, professor of nervous diseases and electrotherapeutics in the University of Michigan, died on December 14 at the age of fifty-eight years in a private sanatorium in Baltimore, where he had gone to have an operation performed.

Dr. George H. Sholters of Washington, D. C., died on December 14 at the age of fifty-eight years. He was born in Burlington, Vt., and after receiving a legal education and practising law for some years in Albany, was graduated in medicine and began practice in Washington. Some years ago he was made examiner in the Patent Office.

Dr. Ira P. Coller of Adrian, Mich., died on December 9 at the age of forty-one years. He was graduated from the Michigan College of Medicine in 1903.

Dr. Charles W. Bowker of Bernhardston, Mass., died on December 10 at the age of eighty-two years. He was graduated from the Berkshire Medical College at Pittsfield in 1854, and after practising in several Vermont and Massachusetts towns became a contract surgeon in the United States Army. He began practice in Bernhardston in 1865 and had remained there ever since.

Dr. S. W. Turner of Chester, Conn., died on December 9 at the age of eighty-five years. He was a graduate of Yale University in the class of 1842 and received his medical degree from the Yale Medical School four years later. He had held many professional and official positions.

Dr. C. C. Bradley of Manchester, Ia., died on December 8 at the age of sixty-four years. He was born in Alleghany County, New York, and was graduated from the Bellevue Hospital Medical College in the class of 1867.

Dr. Hiram R. Mills of Port Huron, Mich., died of heart disease on November 29 at the age of sixty-nine years. He was born in Salina, Mich., and received his medical education in the University of Michigan, graduating in 1866. He was for three years in the regular army and held the position of post-surgeon at Mackinac. In 1871 he came to Port Huron and practised until about five years ago, when he was made surgeon at the Soldiers' Home. During his residence in Port Huron Dr. Mills served as pension surgeon, marine surgeon, supervising inspector of the immigrant service, and health officer.

Dr. Alonzo Garcelon of Lewiston, Me., died from accidental asphyxiation by gas on December 8 at the age of ninety-three years. He was born in Lewiston and entered Bowdoin College in 1832. His medical education was obtained at the Dartmouth Medical School and the Medical College of Ohio at Cincinnati. In addition to his eminence in practice, Dr. Garcelon was a prominent figure in public life, and had been president of the American Medical Association, member of the State Legislature and Senate, surgeon-general of the State during the Civil War, and Governor of the State.

Dr. Joseph D. Nash of Philadelphia died of apoplexy on December 10 at the age of seventy years. He was born in Plumstead, Bucks County, and was graduated from the Jefferson Medical College in the class of 1865. He was secretary of the Philadelphia County Medical Society.

Dr. Thomas F. McCleary of Brooklyn died on December 15 at the age of thirty-six years. He was graduated from the Long Island Hospital Medical College in 1893, and was visiting surgeon to the Bushwick, Eastern District, and Williamsburg hospitals.

Dr. J. H. Keever of Oak Cliff, Texas, died on December 8 of cerebral hemorrhage. Dr. Keever was born in Catawba County, North Carolina, in 1869, and came to Texas when about twenty years of age. He was a graduate of the Baltimore Medical College and took a post-graduate course in the College of Physicians and Surgeons in this city.

OUR LONDON LETTER.

(From Our Special Correspondent.)

EVOLUTION OF STREPTOCOCCI—CLINICAL STUDY—GENERAL MEDICAL COUNCIL—NEW LORD MAYOR'S HOME FOR CRIPPLES—HOSPITAL SUNDAY FUND—HOSPITALS; MANCHESTER FOR SKIN, MIDDLESEX, CHELSEA—OBITUARY.

London, November 30, 1906.

The Horace Dobell lecture for this year was delivered on the 15th inst., by Dr. F. W. Andrewes of St. Bartholomew's Hospital, and in it he endeavored to lay down the history of the evolution of the streptococci. Starting with the assertion that "no biologist nowadays believes in the absolute fixity of species," he pointed out that there are three modes of life among bacteria, viz., those feeding (a) on minerals, (b) on dead organic matter, (c) on living organic matter, these last being true parasites. There are in class (a) the nitrifying bacteria at this day, but most of these organisms have progressed to (b), and some have specialized as far as (c). The streptococci have cut themselves adrift from mineral food and grow best under such saprophytic conditions as are found in the alimentary canal of man and animals. Dr. Andrewes had found them far more abundant there than *Bacillus coli*. Inasmuch as bacteria are of far greater antiquity than animals, these streptococci or their antecedent forms must have waited for ages for the chance of being swallowed, the fortunate individuals at once adapting themselves to their new environment. Many varieties remain at this stage, but some have advanced to the parasitic stage, and are pathogenic. Dr. Andrewes here described the means of the body for dealing with these intruders, phagocytosis, opsonins, etc. He infers that certain common streptococci have developed into weak facultative parasites, but are not yet able to attack healthy tissues. They cannot produce acute suppuration, but they can and do multiply in the blood of the dying, and further can establish themselves in weak spots in the body, where moisture is lowered and cause a chronic inflammation. The final stage of the streptococci shows them with active aggressive powers (*e.g.* the *S. pyogenes* and pneumococcus) against the defences of the body. These properties, Dr. Andrewes said, must be due to natural selection, and he gave a picturesque account of the struggle for existence between them and the defensive mechanisms. But he admitted a difficulty: it is not a question of their taking an unoccupied nook. Pathogenic bacteria do not permanently establish themselves; they succeed only for a time, and the fight ends either by the extermination of the invaders or the death of the host. If they fail they are not driven back, but perish—every one. So if they succeed it is only a useless conquest, for they are just as surely exterminated in the orgy of putrefactive processes which follows the death of the body. This difficulty, Dr. Andrewes held, was apparent rather than real, and he calls in the millions of years for the body to perfect its defensive mechanisms against bacteria, and says it is inconceivable that the first assaults of these organisms occurred when the defences were fully developed, for these last must have been evolved in response to the assaults. He added that these views hold good for all pathogenic organisms. An infective disease is therefore a battle between the two opposing forces, which ends now in the triumph of one side, now of the other. The business of the doctor is to turn the scale, if he may, against the invader. It is not very long since the efforts of the body were mistaken for the essence of the disease and war waged against fever and inflammation. We have begun

to realize that the reactions may be on our side and the day has begun to dawn when we may do more than follow the expectant treatment. We can, said the lecturer, "at times directly assist the patient in the development of antibodies against the persons or the poisons of his enemies. We can even present him with ready-made antibodies where he has not time or power to elaborate them for himself."

In his second Fitzpatrick lecture Dr. Norman Moore gave prominence to the study of clinical medicine in Ireland. The object of his lectures was, as he stated, to make clear the growth of clinical study in the British Islands from its commencement to the time when it was fully established as an essential part of the work of all who pursue any part of medicine. Yet, having first described the attainments of Sir T. Molyneux, the first great figure in medicine in Ireland, he promised to consider the earlier state of medical knowledge there and diverged into the history of learning in that country, including the medical branch. Here the lecturer gave many interesting particulars which will be read when the lectures appear, as by the endowment they must do, in book form, and will strongly appeal to all who appreciate such historico-literary learning. Irish medieval literature, beginning with the introduction of writing, lasted as long as books were circulated in manuscript only. The language was never, like Anglo-Saxon, permeated by other tongues so as to lose its identity, and it gives us now a preserved specimen of a literature unaffected by the printing press.

The early Irish physicians had brethren in Wales and Scotland, and of these the lecturer also gave particulars. But I pass on to Edinburgh University, which derived the medicine which made it famous from Holland. Its systematic teaching began with the first Monro, who studied under Boerhaave in 1718, and afterward lectured for thirty-nine years. He edited in 1732 the first volume of "Medical Essays and Observations Published by a Society in Edinburgh." Alston, Rutherford, Sinclair, Plummer, and other Edinburgh physicians were pupils of Boerhaave, whose aphorisms were published in 1708, to hear whom men flocked to Leyden from all parts.

Though the followers of the Leyden school seemed to be more on the lookout for something startling than those of Glisson and Sydenham, who were content to mark and describe every circumstance of a case, yet the effect of the teaching of Boerhaave and of the Edinburgh University, which was derived from him, was to increase the enthusiasm for clinical observation. Clinical methods have since been elaborated and improved, but, concludes the lecturer, it is for the physicians of the present day to see that the precise observation of disease at the bedside is never displaced in teaching or practice by other studies.

The General Medical Council began its winter session on Tuesday, when Dr. MacAlister delivered another presidential address. In the course of it he mentioned that when in Canada at the meeting of the British Medical Association he was able to meet ministers of the crown and other influential persons interested in medical reciprocity between Canada and the mother country. He had reason to believe that explanations he had given in reply to inquiries had been serviceable in removing certain misconceptions. He had since heard that in one province active steps were now being taken to bring about mutual recognition of medical qualifications.

The Council is still sitting, but a good deal of work has been got over, and it is hoped the present session may be a short one. A proposal to obtain a report on the advisability of dispensing with systematic lectures in the schools did not receive much support. A motion to ask the examination committee for a report on the inclusion of clinical and practical work in midwifery and gynecology at qualifying examinations was adopted. Alterations in the standing orders were considered and part of the penal work has been concluded.

The new Lord Mayor, Sir William Treloar, has determined to signalize his year of office by establishing an institution for the relief of cripples. He appeals for £60,000 for the purpose. The King and Queen have each sent £100, and the success of the scheme seems assured. Sir William and Lady Treloar have long been known as deeply interested in cripples. For some twenty-seven years they have obtained subscriptions for sending Christmas hampers to crippled poor children.

The Council of the Hospital Sunday Fund met yesterday, the Lord Mayor presiding. There was, it was stated, a falling off in the church collections of above £4,000, compared with the previous year. The late Mr. George Herring's donation was £11,000. One of his executors reported that the fund would benefit under the will by a sum of about £600,000. In the event of the "back-to-the-land" scheme of the Salvation Army failing, there would be a further sum of £60,000, but it was hoped this would not occur, as Mr. Herring was deeply interested in its success.

On Wednesday, Sir Thomas Barlow, speaking at the opening of the Manchester New Hospital for Skin Diseases, commended the committee for fitting up a room for research which he held was the very best way to put down quackery, so rampant in connection with skin diseases. The English people, he declared, though very benevolent, had not yet learned to give money for research as the people across the Atlantic had. Practical as the English were, they had not yet got hold of the importance of research in connection with the study of disease.

At a meeting of governors of the Middlesex Hospital yesterday it was said that to meet current expenses the committee had been obliged to borrow. A donation of £2,500 had been received and a legacy of £5,000 for the cancer fund had been announced. Nevertheless, the needs were urgent. The special committee appointed last year had been able to discover methods of reducing expenses by nearly £2,000. The researches in the cancer laboratories were being carried on with unwearied vigor.

The governors of the Chelsea Hospital for Women yesterday resolved on an alteration in their by-laws whereby all the members of the medical staff, whether physicians or surgeons, will in future be termed surgeons. It was suggested that other institutions would probably follow suit in recognizing to how great an extent gynecology has become surgical. During the year the hospital had expended £1,600 in alterations and repairs to render its sanitary condition perfect.

Dr. Symes Thompson, consulting physician to the Consumption Hospital, Brompton, and Gresham professor of medicine, died on the 24th inst., aged 69. He was a son of the late Dr. Theophilus Thompson, F.R.S., whose lectures on consumption formed an authoritative work in his day. Dr. Symes Thompson took M.D., London., 1860; M.R.C.P., 1862, and was elected to the Fellowship in 1868. Since 1875 he has given the Gresham lectures, but though fluent and possessed of a good voice, he could not do more than fulfill the duty of the endowment which has become a sinecure. He was a genial, courteous, and upright colleague.

Dr. Andriezen has died at the early age of 36. He had achieved so high a reputation as a neuropathologist and psychologist that it seems surprising he was not older. As a student he carried off many distinctions, including the Liston gold medal, for research in pathology. He took first class on honors at the University of London and worked strenuously at scientific research ever since. He had seen asylum work, and of late helped in the cancer laboratories of the Middlesex Hospital. His contributions to biology, neurology, and pathology are too numerous to mention, and you must know many of them.

Dr. E. B. Ferguson, surgeon of the Cheltenham Hospital, died on Tuesday in a tragically sudden manner. He was in the midst of an operation for hernia and had resected a long length of gangrenous intestine. He was just tying the mesentery when he fell dead in the presence of the house surgeons assisting him. In 1901 he was president of the British Medical Association, meeting at Cheltenham, and greatly contributed to its success. He had suffered for some time from heart disease.

Mr. Everett Norton, anesthetist for many years to the Middlesex hospital and greatly esteemed by the staff, died suddenly on the 17th inst. He slipped and fell down as he was leaving a patient's house, wounding his face, which bled profusely. He was taken home, and went to bed, but soon collapsed and died. He had suffered from heart disease, but had seemed to improve of late.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

TYPES OF DYSENTERY BACILLI—LATENCY AND RECURRENCE IN MALARIA—CONGENITAL ABSENCE OF THE VERMIFORM APPENDIX—BERIBERI—CHOLERA—ATTACK ON THE HEALTH BOARD BY THE NATIVE PRESS—PERSONAL.

MANILA, October 15, 1906.

THE regular monthly meeting of the Manila Medical Society was held October 1, 1906, at 8:30 P. M., at the St. Paul's Hospital. A paper entitled "The Types of the Bacilli of the Dysentery Group," prepared by Dr. Ohno, a Japanese physician of this city, was read by the secretary. The author was unable to be present, owing to an attack of cholera. The opinions expressed in the paper agreed very closely with those advocated by Shiga. The next paper, entitled "The Relation of Intracorpuscular Conjugation in the Plasmodia of Malaria to Latency and Recurrence," was read by Captain and Assistant Surgeon

Charles F. Craig. The author reaffirmed the views previously expressed in his published articles.

Drs. H. T. Marshall and Ralph T. Edwards, pathologists of the Bureau of Science, presented a specimen of an intestine which showed a congenital absence of the vermiform appendix. Dr. Marshall stated that literature revealed only six cases of this kind, and that four of these were not very well authenticated, thereby emphasizing particularly the rarity of the specimen. In Dr. Marshall's case every precaution was taken to demonstrate conclusively that no rudimentary appendix existed. Careful microscopical sections were made, the examination of which showed that no glandular or other structure characteristic of the appendix could be demonstrated. Drawings and photographs were also exhibited, which seemed to demonstrate that no appendix existed.

Dr. J. W. Madara, Physician-in-Charge of the Iwahig Penal Settlement on the Island of Palawan, reports that there has been much beriberi among the prisoners at that settlement, and that several buildings seem to have been infected. It was only after removing the prisoners to other quarters that the epidemic of beriberi was brought under control, thus adding additional evidence to the theory held by a number of distinguished writers, of house infection. The epidemic of beriberi which occurred among the lepers at the Culion Leper Colony has practically disappeared. In this connection it is interesting to note that during the first month of its existence it was confined to those persons who were brought from Cebu, and only after it had been present among them for a month or more, were cases noted among the lepers at Culion who came from other islands.

The cholera situation in Luzon is improving very rapidly. For the first half of October there have been in Luzon only 107 cases and 73 deaths, as against 185 cases with 145 deaths for the preceding two weeks. In Manila there were 15 cases with 13 deaths, as against 30 cases with 23 deaths for the last two weeks of September. In Iloilo the situation is not so encouraging. While there has been no great increase in the number of cases, yet more towns are gradually becoming infected. For the two weeks covered by this report there were 493 cases and 391 deaths. The lack of better success in combating the epidemic in that province is attributed by the Bureau of Health to the fact that many of the native physicians and other influential persons persist in stating that the disease is cholera nostras and not true cholera. These statements are made in spite of the fact that a short time ago, in a town of 2,000 inhabitants, more than 80 people died in the course of a few days.

The quarantine which has been imposed upon vessels leaving the province of Iloilo has given rise to considerable friction, and much dissatisfaction on the part of residents, but in view of the fact that it has proven entirely effective, so far as the spread of the disease by water is concerned, the health officials have not felt warranted in lifting the same.

During the past two weeks the native press of the city of Manila has been making severe attacks upon the Bureau of Health, it being claimed that the efforts made in the eradication of cholera had proven a most lamentable failure, and that Filipino physicians should be placed in charge, who would demonstrate their ability to handle a situation of this kind. It is alleged that the origin of these attacks may be ascribed to an alleged refusal of the Bureau of Health to appoint a number of native physicians to positions formerly held by Americans. The justice of the attacks and the ground upon which they rest may well be judged from the fact that there are no Filipino physicians upon the Civil Service eligible list, and from the statements made by the press representatives, to the effect that it would be much better to let cholera sweep unchecked and unhindered through the islands and have it over with, than continually to block its path with sanitary measures. The fact seems to have been lost sight of, however, that only dozens have died during the present epidemic, where hundreds and even thousands died in the previous epidemics, and that the disturbance to commerce and to business has been reduced to a minimum, and if it were not for a sensational press the average inhabitant would scarcely know that cholera was present. These ungrounded attacks only have the effect of giving expression to the opposition which seems to exist inherently in the Malay, to sanitary measures, and thereby the cause of public health is retarded and the work of the Bureau of Health made correspondingly difficult. Owing to the long-continued strain undergone by the medical and nursing staff at the San Lazaro Cholera Hospital, due to the great amount of continuous work caused by the cholera sick, the nurses particularly have become exhausted, so that it was almost imperative to provide means whereby rest and recreation might be had. In view of the fact that there were only a few patients left in the San Lazaro Cholera Hospital, it was deemed advisable to close the same for a while, at least, and have the few remaining patients treated at the Santiago Hospital of the city of Manila.

Major and Surgeon Edgar A. Mearns of the United States Army, who has been Chief Surgeon of the Department of Mindanao, has been relieved from duty in the Philippines and will proceed to the United States by first available transportation. Major Mearns is credited with being one of the leading naturalists in the army, and during his stay in the Philippines he has found a number of new specimens of rats and other animals which have heretofore not been described.

Dr. Thomas R. Marshall, the Chief of the San Lazaro Hospitals Division of the Bureau of Health, who has been engaged in health work with the Civil Government for the past four years, has resigned and returned to the United States, where he expects to engage in the practice of medicine at Richmond, Va.

Progress of Medical Science.

New York Medical Journal, December 8, 1906.

Relaxation of the Sacroiliac Synchondroses.—Four such cases are detailed by J. Dunlop, who believes that this injury results from accidents far more often than is generally recognized, and that the cases due to trauma are among the serious ones of the lesion. While the etiological factors may be numerous, the symptoms present a distinct type. Backache is nearly always the complaint. The usual history, especially, seems to date back to a definite injury, since which time there has been difficulty in all motions or postures requiring a movement of the sacral region of the spine, such as sitting, getting up and down, stooping, or even lying, especially when a soft bed is used and a certain amount of anterior bending of the spine is produced, and a relaxation of the lumbar curve causing a strain on the sacroiliac ligaments. On inspection there are found in varying combinations sacral prominence, rigidity of spinal muscles, lateral spinal curvature, obliteration of the normal spinal curve, and swelling due to the distention of the joint with fluid. On palpation there are noted tenderness to pressure over the joint and mobility. Differential diagnosis is called for from osteoarthritic spine, chronic sciatica, neurasthenic spine, lumbago, muscular rheumatism, and typhoid spine. Treatment consists in the use of a support which will properly hold the synchondroses in place.

Psychical and Medical Treatment of Conditions Underlying Gastric Peptic Ulcer.—According to M. R. Barker, gastric peptic ulcer is the culmination of a series of morbid events or underlying conditions, the scientific treatment for which would prevent ulcer formation. Worry, anxiety, heredity, dietetic errors, habits, etc., may, any or all of them, lead to a neurosis. This causes hyperchlorhydria, and this in turn the ulcer. Our starting point, then, is to prevent the neurosis. Care of the growing child should eliminate the factors which so often conduce to this result. A special system of psychological teaching may be instituted in our schools, so that the viciousness of morbid mental processes is impressed on the pupils, and they are taught how to grapple with the problems of school life, and after this in life's work, without apprehension; how the greatest successes are to be attained in life's struggle, with worry eliminated; that if they are to attain to their highest capabilities they must rise to a plane higher than that dominated by these morbid conditions. They should be taught to become mental masters of these morbid conditions, and never become their prey. Present pedagogical methods foster, promote, and develop these morbid instincts. Children are constantly overworked. If the hyperchlorhydria becomes established the same course of treatment should be persisted in, in changing morbid mental conditions change in environment will often work wonders. Some cases of hyperchlorhydria arise from overeating during periods of comparative relaxation, though the quantity of food taken may be all right for the strenuous periods. In some there is a hyperesthesia of the gastric mucosa. In some the condition arises from the abuse of condiments and alcohol. In all cases of gastric ulcer, however, one thing is always indicated, and that is rest. Whatever else may be done, this is the most important. This is secured by rectal feeding, and very little if any stomach alimentation for a week or two in aggravated cases. The patient should remain in bed during all this time. In conjunction with this any of the methods detailed may be adopted which in the judgment of the internist best suits his case.

Multiple Chancres.—After a reference to various authors who have written on this subject, F. C. Knowles

reports the case of a man, aged twenty-eight, with five undoubted penile chancres. The patient stated that two of the lesions appeared synchronously, the third in another week, and the remaining two in two weeks more. As far as could be learned, the period of primary incubation was about a month. The subsequent appearance of rash and the coincident adenopathy rendered the diagnosis certain.

Pyelonephritis.—A general paper on this subject is presented by E. Fremont-Smith, who quotes freely from various authors. He refers especially to the work of Lehr and Young, who have collected from literature reports of four cases, showing pure culture of the typhoid bacillus, and who report two cases in which the kidney manifestations were quite latent for some years after the fever had run its course. In the first of these two cases pyuria was noted at the beginning of an attack of typhoid in 1893. In 1898 the bladder was aspirated, and pure typhoid culture found in the urine, and it was then considered solely a bladder infection. In 1903, ten years from the original fever, the patient by accident discovered a mass in the right side. Up to this time his only symptoms had been frequent ill-defined fevers and lassitude. The urine was acid, and urinary symptoms were wanting. Nephrotomy revealed a large pus kidney, with pure typhoid cultures and a calculus, in the center of which was discovered the proteus vulgaris in pure culture. Thus the original infection of the proteus, which was responsible for the stone, had died out and been supplanted, on a favorable soil, by the typhoid bacillus during the fever attack. Manifestly the proteus developed stone, preceded the attack of typhoid. Recovery followed a final nephrectomy. The second case reported exhibited no physical signs or symptoms of kidney infection barring general low health for years, following an attack of typhoid fever, until six months before he entered the hospital, when he complained of slight irritation after urination, without unusual frequency, and of nausea, and vomiting. The urine was slightly acid and purulent. Death supervened before operation could be done, but autopsy revealed pure culture of typhoid bacilli from the pus of the kidney and a calculus, in the center of which was a nest of typhoid bacilli.

Journal of the American Medical Association, December 15, 1906.

Myasthenia Gravis.—Three cases are reported by C. E. Riggs, illustrating the bulbar and the ophthalmoplegic types of the disease. Although there were antecedent pathological conditions in two of the cases, Riggs considers the etiology of the disorder as still unknown. In two of his cases there was external ophthalmoplegia, and the "nasal smile," noted by Gowers, was marked in all three. The myasthenic reaction—the tetanizing of the muscle by faradism—was present in all three cases, and while not pathognomonic, its occurrence is significant and valuable for diagnosis. The greatest danger in diagnosis is that of mistaking the condition for hysteria, especially if the color reversal and other symptoms of hysteria are present, as in a case reported by Burr. Riggs thinks that the condition is best explained by assuming a toxin in the blood affecting the lower motor neuron, and refers to Taylor's suggestion, based on a not infrequent pathological finding, that this toxin is due to a diseased thymus or to an abnormal lymphoid tissue infiltration throughout the body and muscles, and that in myasthenia we are dealing with a disorder in a certain sense the converse of myxedema. Treatment has been usually ineffective, but in one of his cases, under his care for months, he found the most efficient agents to be strychnia, gentle massage, and galvanism.

Treatment of Nephritis.—F. M. Johnson is an advocate of the more extended use of lavage of the renal pelvis as an addition to the usual medication in the treatment of certain types of kidney disease. Lithemia and oxaluria, resistant to other methods, will often yield to lavage of the kidneys with warm boracic-acid solution; in pyelitis he advises thorough lavage and local medication before attempting a major operation, and in the earlier and milder stages of subacute parenchymatous nephritis and of chronic catarrhal nephritis, the added soothing and healing influence of lavage, given with due care and attention, seems to have a beneficial effect. Cool distilled water is best for the preliminary washing of the bladder before using the cystoscope, and for the kidney, whatever solution is employed, it should be warm and, in the beginning, mild in strength. Small quantities are better than too large.

The Treatment of Asthma.—De Lancey Rochester believes that most cases of asthma are due to neglect of catarrhal affections of the upper air passages in early life, producing pathological hypertrophies of the turbinates, of Luschka's tonsil, and of the faucial tonsils. These conditions tend to bring about a condition of pulmonary emphysema with imperfect oxygenation, resulting in the autointoxication, revealing itself in the asthma. Cases developing later in life are due to imperfect metabolism and autointoxication, the causes in such cases being the habits of life of the individual, among which Rochester includes overeating, constipation, sedentary life, and insufficient use of the lungs in an imperfectly oxygenated atmosphere. The chief evidences of the autointoxication are the degree of acidity of the urine and the degree of indicanuria present. He has never had a case of asthma under observation in which there was not, when first seen, a strongly acid urine which deposited on centrifugalization urates and uric acid or calcium oxalate, and showed a pronounced reaction for indoxyl sulphate. The treatment should consist mainly in proper attention to the upper air passages and nutrition in early life. If seen later, much can be done to prevent recurrence of the attacks by correcting obstructions in the upper air passages and other sources of irritation of the nervous system; but, above all, by so regulating the intake of food and stimulating the elimination of waste products that a proper metabolic balance can be maintained.

Malarial Hemoglobinuria.—Fourteen cases are reported and discussed in detail by W. V. Brem. The general results of the study of these cases are summarized, in substance, as follows: 1. A febrile affection resembling the estivoautumnal type of malarial fever was the only etiological factor discoverable. Previous attacks of malaria seemed to furnish a favorable ground. Quinine was not an etiological factor, either predisposing or exciting. The evidence favors the estivoautumnal parasite and not a special organism as the cause. 2. The symptoms and signs may be very mild and the grave condition be revealed only by the urinary examination. A history of dark or bloody urine can almost invariably be obtained. 3. The degree of fever bears no relation to the hemoglobinuria or albuminuria. A post-hemoglobinuric fever of a peculiar type occurred in four cases; it does not yield to quinine. 4. Blood examinations show that the primary event is destruction of the red blood corpuscles, with hemoglobinemia and subsequent hemoglobinuria. Anemia is exceedingly rapid, as is likewise recovery. 5. In well-defined cases particularly, an absolute diagnosis can be made by macroscopic examination of the urine, combined with the test for albumin. In border-line cases the hemoglobin test is necessary for an absolute diagnosis, but a probable diagnosis can be made from a brownish urine with 20 per cent. albumin or more. 6. The mortality was two in fourteen cases (14.3 per cent.). 7. A correct prognosis in individual cases is very difficult. 8. Intramuscular injections of quinine seem to act specifically. The best method is thought to be the injection of 10 grains every four hours for the first forty-eight hours (15 grains may be given for the first three or four doses), and then smaller doses may be given by the mouth unless vomiting prevents. Quinine bihydrochloride in an excess of acid is more suitable than quinine bimuriate with urea for intramuscular injection.

Multiple Fibrosarcoma of Tongue Treated With Trypsin.—F. H. Wiggin reports a case in which a patient with fibrosarcoma of the tongue was treated with trypsin, pancreatic extract, and amylopsin. A capsule containing pancreatic extract was given an hour before each meal. The tumor apparently ceased to increase in size and remained stationary until the injections were given daily, and the dosage increased to 15 minims. The dosage was gradually increased to 40 minims daily, and then the patient began to complain of headache and constipation, and looked anemic. Treatment was discontinued for a time, and then ampoules of trypsin, pancreatin, and amylopsin were given. For a time this seemed to bring about a decided improvement, but as the weather was very hot and trying at this time, the treatment was discontinued at the patient's request, and soon after she passed from observation. There were some differences of opinion among pathologists regarding the malignancy of the tumor.

Bradycardia in Appendicitis.—M. Kahn calls attention to slow pulse as a symptom of latent or incipient gangrene in appendicitis. How often it occurs cannot be said with present data, but it has been so frequently met in his series of cases that in the last six he made the diagnosis before operation on this symptom alone. It is true that we sometimes see cases with tachycardia, but he cannot recall encountering bradycardia in a case of appendicitis that did not present gangrene. Of course, the normal pulse of the individual must be known to avoid mistake. He attributes the symptom to some ptomain absorption acting on the cardiac centers or ganglia, such as is not infrequently seen in jaundice and chronic digestive disturbances. It is not akin to the slow pulse of convalescence from some acute fevers, which is probably due to failure of reactive power or inanition. The importance of the symptom, if it is found to be generally present, can hardly be overestimated.

The Lancet, December 1, 1906.

Rupture of the Trachea with Complete Detachment of the Left Bronchus Without External Injury.—The patient of J. L. Barford was a boy of four years, who was

run over by a heavy wagon, brought to the hospital in twenty-five minutes, and who died twenty minutes after admission. During this period the symptoms were dyspnea, intermittent cyanosis, affecting chiefly the head, neck and arms, the other bodily areas being of good color, hemoptysis (arterial), restlessness, and surgical emphysema. He died in a condition of extreme cyanosis and heart failure. On autopsy a mass of dark clot was found around the great vessels at the root of the heart, and, the heart having been removed, the left bronchus was found to be completely detached from the trachea at the point of bifurcation of the latter. The tongue, larynx, and trachea having been separated from above downwards and removed with the lungs, a rupture of the trachea was found extending from the point of bifurcation for fully an inch up the posterior surface along the left extremities of the tracheal rings, which themselves were uninjured. The detached left bronchus was also torn down its length posteriorly. The esophagus and spine showed no injury. The stomach was very full of food and altered blood. Externally the chest showed no changes, except a slight persistence of the emphysema toward the neck. The author notes that the causes of death are of interest. The dyspnea was probably due to combined causes, viz., (1) the partial nonapposition of the trachea and left bronchus, the left lung being thus thrown partly out of action; (2) blockage of the bronchi and bronchioles of both lungs with blood; (3) impaired action of the left side of the chest owing to fractured ribs; (4) deficient expansion of the left lung from bruising and consolidation with blood, and (5) impaired action of the diaphragm from acute overdistention of the stomach, vomiting of food, and swallowed blood being possibly prevented by impairment of the nervous mechanism. The cyanosis was peculiar in affecting chiefly the head and upper extremities, indicating obstruction to the superior vena cava rather than a more general derangement of circulatory or respiratory functions. Its intermittent character could be explained by the fact that the child in his efforts at times succeeded in bringing the bronchus and trachea into better apposition again. The fact that the blood escaping from the mouth was brightly arterial, even during considerable cyanosis, seemed to indicate some injury to the lower air passages. The restlessness, combined with the cyanosis and crying out, resembled very markedly the signs of pulmonary thrombosis, and these features were likely enough due to pressure of blood (and air) on the thin-walled pulmonary artery. The author also suggests that the escape of air from the trachea may have led to its compression from without by the accumulation of the air within the faucial sheath surrounding the trachea and esophagus. Another possible factor was pressure to, or injury of the vagi and cardiac plexuses.

Phlyctenular Ophthalmia.—J. B. Nias and L. Paton recall the fact that this form of ophthalmia has been referred to infarctions of dead or attenuated tubercle bacilli, and have recently tested the opsonic power of the blood against the tubercle bacillus in nearly 200 specimens taken from fifty different patients. They find that the blood of such patients behaved in a manner altogether typical of a definite tuberculous infection; that is to say, its activity in opsonic action on the *B. tuberculosus* fluctuated in a marked and definite manner above and below the normal, according to the progress of the case. They note that the blood of a patient suffering from genuine phlyctenular ophthalmia is generally found to be markedly deficient in opsonic power to the tubercle bacillus, but not to other bacteria, such as the staphylococcus, at the outset of the case, but if the patient be adequately treated (without recourse to tuberculin, be it understood) the opsonic index rapidly rises and reaches a maximum coincidently with the healing of the ulcers. It then begins to fall rapidly, and in a few days is far below the normal, as if from exhaustion of the mechanism. At this low figure it will remain if the observations be continued for an indefinite time, and if, as so often occurs, a relapse takes place the same sequence of phenomena will be reproduced. In a minority of cases, generally in older and more vigorous subjects, the opsonic index as regards the tubercle bacillus will be found to have risen already much above the normal. Here it will remain with temporary falls till healing occurs, and then take a terminal drop as in the former category. They have not yet met with a single exception to this course of phenomena in phlyctenular conjunctivitis. The authors present condensed histories of several types of cases, and earnestly request that the matter be taken up by other laboratory workers, so that their results may be either verified or disproved.

Lepra Tuberosa Treated with Chaulmoogra Oil.—One case is detailed at great length by J. A. Thompson. The patient was a soldier of fifty-eight years, whose disease came on in 1904. For some five months he was treated with gurjun oil, but without benefit, and the author states that this remedy has been valueless in his hands in this particular disease. At the end of the five months the chaulmoogra oil was begun in fifteen-minim doses three times daily. His daily dosage was increased, and in the course of the next few months varied from 150 to 315 minims. The immediate result was decidedly beneficial, though no claim is made that the case was actually cured. The details of the case must be consulted in the original paper.

British Medical Journal, December 1, 1906.

Intracellular Injections of Quinine in Malaria.—This method of administering quinine is commended by G. F. Darker. He prefers the use of a warm, dense solution of the hydrochloride (neutral salt), and gives the following directions for the preparation of the drug: (1) Place from 7 to 15 drops of water (by choice 10) in a test tube, and add 15 grains of quinine hydrochloride in crystals. (2) Shake the crystals down to the bottom of the tube; the water will be soaked up by the lower crystals. (3) Pass the tube through the flame of a spirit lamp until all the crystals have gradually dissolved; the fluid should then be made to boil. (4) The tube is now allowed to stand with a sterile cover placed over its mouth, until the end containing the fluid feels "just warm" to the hand (that is, 100° F.). The whole of the fluid should now be injected with an ordinary hypodermic syringe under aseptic precautions either into the cellular tissue under the skin of the anterior abdominal wall, in the case of a child able to walk, or into the deep tissues of the outer side of the thigh in the case of a baby in arms. The aperture made by the needle may be closed with a saturated solution of gum mastiche in rectified spirit, and a piece of lint applied. The quinine solidifies in the tissues, and is absorbed in about two months, during which time the child's general appearance greatly improves. When a number of children are being injected a sufficient quantity of the crystals can be kept in solution by placing the test tubes containing them in a water bath at 100° F. Care must be taken that the temperature of the fluid, even when in the syringe, has not fallen much below 100° F., otherwise solidification will take place; should this happen, warmth will again liquefy the crystals, which can then be washed out. The author notes that dense solutions of the acid salts of quinine such as are used for intramuscular injection in malignant malaria disorganize the tissues, and suggests that with malignant cases one grain should be injected in ten drops of water, and that several such injections should be made at the same time if necessary.

The Use of Digitalis in Valvular Disease of the Heart.—The uses of digitalis in valvular cardiac disease are summarized by E. H. Colbeck. He declares that digitalis should seldom, if ever, be given in cases of aortic regurgitation which have developed during or after middle life, since under these circumstances the ventricular wall is seldom sound. It should never be given in cases presenting evidence of myocardial degeneration or disease. If complete rest is obtained the drug is permissible, and even beneficial to a certain point in young and otherwise healthy adults who show signs of circulatory failure, more especially when aortic lesion is combined with mitral incompetence. The drug should be discontinued for some time before exercise is resumed. Neglect of this precaution is often followed by rapid ventricular failure and sudden death. In aortic stenosis the drug is contraindicated, as in this case the augmentation of the tonus of the heart and peripheral vessels (caused by the remedy) would merely increase the obstacle against which the left ventricle has to contend. In mitral incompetency the benefit of the remedy is universally admitted. On the left side of the heart, a rise of cardiac tonus resists the overfilling of the ventricle, which is the initial effort of the valvular insufficiency, while subsequent hypertrophy maintains the tonus of the ventricle and promotes the expulsion of its increased content. On the right side of the heart, a rise of tonus and consequential hypertrophy enable the right ventricle to cope with the increased resistance in the pulmonic circuit, and, by maintaining the blood pressure in the pulmonary veins and left auricle, it resists the reflux through the mitral opening and insures an adequate supply of blood to the left side of the heart. In uncomplicated cases of mitral stenosis the supply of blood to the systemic circulation tends to become increasingly restricted. A rise in the tonus of the left ventricle and peripheral vessels would still further diminish the charge of blood delivered to the aorta. No doubt the effect of increased cardiac tonus on the right side of the heart would be of benefit, provided the blood supply to the left ventricle could be thereby augmented. It may be inferred, therefore, that digitalis can be of no benefit to mitral stenosis in the absence of failure of the right ventricle, and in this event, so soon as the pulmonary blood pressure has been raised to the point at which the maximum charge of blood is delivered to the left ventricle, the drug would again act prejudicially.

Spirochetes in Hemoptysis.—A case of hemoptysis with numerous spirochetes in the sputa is reported by

C. W. Branch. His patient was a negro man of fifty-nine years, who was admitted to hospital with profuse hemoptysis. Examination showed a cavity below the right clavicle. Both legs showed tertiary scars. Malarial organisms were found in the blood. No tubercle bacilli were found in the first examination of the sputum, but numerous spirochetes were found which stained with methyl blue. No ova of parasites were found in the fresh sputa. On autopsy a collection of bloody pus was found under the sternum and a small abscess in the spleen. Smears from the pus under the sternum and the spleen abscess stained with Giemsa showed no spirochetes nor other organisms. In the blood from the cavity and in the bloody mucus from a small bronchus of the base no spirochetes were found. Squash preparations of tuberculous tissue from apex and base showed tubercle bacilli, but no spirochetes. Smears of the sputum taken before death were again examined, and tubercle bacilli were found. No spirochetes were found in the subclavicular cavity, in the lung tissues, or in the mucus from a small bronchus. From their position and associations in the sputum, as well as from their number, it is impossible that they were derived from the mouth. Their distribution in the sputum was very irregular, some smears containing none at all. While the author does not claim that the case proves anything but a saprophytic existence of the spirochetes in the large bronchi, he notes that their presence gives a peculiar viscous character to the sputa.

The Comparative Frequency of Impaired Nasal Respiration as an Antecedent to Pulmonary and Extrapulmonary Tuberculosis.—W. C. Rivers notes, with reference to this association, the following facts, his theses being based on a series of previously reported cases. (1) The condition in question presented itself nearly twice as frequently amongst some male phthisical cases as in a series of nontuberculous men, comparable in respect of age and of occupation and social condition. (2) Whereas several cases of nasal and of nasopharyngeal abnormality are known to be hereditary, a family history of pulmonary phthisis was found to be much more frequently given (except among those of very poor physique) by the subjects of impaired nasal respiration than by others; and this held good of nontuberculous as well as of phthisical males. It was therefore concluded that the initial channel of infection in many cases of pulmonary tubercle was almost certainly respiratory. In the foregoing cases, in the course of a comparison of phthisical with nontuberculous males, the percentages of the subjects of impaired nasal respiration were found to be respectively 56.7 and 30.8, and these proportions were found to be inherent fairly uniformly in each 40 or 50 cases examined. Thus it would not seem to be likely that mouth-breathing and "qualitative" impairment of nasal respiration are commoner in cases of extrapulmonary tuberculosis than in healthy people, who constituted the great majority of the nontuberculous males in question. It is concluded that there may exist, as between pulmonary and extrapulmonary tuberculosis, the following etiological point of differentiation—namely, that a certain mode of infection, a prerequisite of which is some abnormality of the upper respiratory tract, obtains more frequently in pulmonary than in extrapulmonary tubercle; and that perhaps, in the latter, it obtains very rarely, or never. As to the exact route of invasion, it must be remembered that there exists a body of evidence fairly conclusive as against direct respiratory infection of lung tissue. Conformably with the theory of intestinal origin, the common way in which the subject of impaired nasal respiration gets infected would seem to be by deposits left by unfiltered air in the mouth or nasopharynx or oropharynx reaching the alimentary tract. The anatomical relations of Waldeyer's ring and the mucous membranes to the lymphatic system may also be invoked.

Berliner klinische Wochenschrift, November 19 and 26, 1906.

Ozena as a Contagious Disease.—Lermoyez believes that ozena is a contagious disease, and in order to make his point he indicates a number of particulars in which the condition may be compared to syphilis and to gonorrhea in its clinical course. He also cites a number of instances that have come under his observation in which children have contracted the disease from each other, or from an infected mother or nurse, and married people have acquired it from a diseased partner. Apparently the intimate contact of constant living together is necessary for the infection to be transmitted, but Lermoyez believes that enough cases are on record in which ozena has developed as a consequence of continued association with another person suffering from the malady to dispel all doubt as to its contagiousness. The author speaks of four different microorganisms which have been described as the etiological agent, but expresses his own belief in the pathogenicity of the coccobacillus to which is attached the name of Perez. The cultures of this organism develop the characteristic fetid odor, and when inoculated into the veins of an animal give rise to atrophic rhinitis. The author accordingly concludes that persons suffering from ozena should observe all possible prophylactic precautions toward other members of their families, especially toward children.

The Protection and Repair of the Perineum.—Apfelstedt describes a method of protecting the perineum from rupture during the passage of the fetal head, which he considers has advantages over those now in use. It is a bimanual procedure, in which the operator, placed at the patient's left side with the left hand on the perineum, controls the advance of the fetal head, while with the right the soft parts under the pubic arch are crowded back toward the nape of the neck of the fetus. When the head is about to be born the patient is instructed to take rapid, deep breaths as forcibly as possible, and by this means the expulsive action of the abdominal muscles is reduced to a minimum. Under these conditions it is stated that the head can be perfectly controlled by the two hands, and be very gradually brought over the perineum and through the vulva at the discretion of the operator. The author also describes a method of perineal repair which requires the use of sutures of silkworm gut armed with a needle at each end. The laceration is opened up by spreading apart the vaginal walls, and one needle is entered at the apex of the V formed by the sides of the laceration. It is carried in a wide sweep through the muscles, and is then brought to the surface of the perineum a short distance from the edge of the tear. The other needle enters the tissues at exactly the same point as the first, but is carried through the tissues on the other side of the incision, and emerges on the skin at a point opposite the first. As many sutures as are required are passed all exactly parallel to this. If the tear is a complete one, the two lowest sutures are so placed as to pass through the ends of the torn sphincter. The author believes that it is safe to remove the sutures on the sixth day after operation.

Münchener medizinische Wochenschrift, November 20 and 27, 1906.

The Transmission of the Percussion Sound.—Hamburger says that the oldest theory relative to the nature of the percussion sound over the lungs was that of Williams, which was published in 1838. This observer considered that the percussion sound was the result of the vibrations of the thoracic wall that were set up through the percussion stroke. If these vibrations were unimpeded the note was loud, but if they were interfered with the note became dull. At about the same time Skoda put forward a different view to the effect that the only factor concerned was the vibration of the air in the lungs. Skoda considered that the chest wall had nothing to do with the formation of the note, and that the flatness obtained over solid organs depended on the absence of any air to be set in vibration. Mazonn in 1852 corrected both of these views by combining them in the dictum that the percussion note is evoked through the vibrations of the chest wall and through the vibrations of the pulmonary air that are set up secondarily. The author is in accord with this supposition, and discusses the physical considerations involved in the production of the liver and cardiac dullness, etc. He believes that vibrations are transmitted from one side of the chest to the other to a much greater degree than is generally believed, and says that, particularly in dealing with children, care must be taken to avoid possible sources of error through contact of the patient's thorax with solid objects. For example, if a child is examined while being held by the mother with one side pressed against her own body the percussion note over that side of the chest will be much duller. In percussing the left axillary region there is often a tympanitic quality to the note, owing to the presence on this side of the air-filled stomach. In order to make comparison possible between the two sides, it is advisable to have an assistant place his hand against the patient's side with the upper border on a line with the lower border of the lung. In this way the transmission of vibrations from the stomach is checked and accurate comparison between the two sides is made possible.

The Blood Examination in Nervous Persons.—Goett gives the results of the blood examination in four neurasthenic young males, which were remarkable owing to the fact that while the hemoglobin was high there was a very marked diminution in the number of red cells per cm. For example, in one case with a hemoglobin of 95 per cent., there were only 2,500,000 erythrocytes to the cm. In these four cases the hemoglobin index varied from 1.17 to 1.9, a result that was entirely incompatible with the general clinical picture. The author considers that errors of technique can be excluded in these cases, and explains the disparity by supposing that sudden vasodilatation took place in these very nervous individuals owing to the prick of the needle, and possibly the sight of the drop of blood. In each case the first drop taken was used for determining the hemoglobin percentage by means of Sahli's apparatus,

and the counts were made on the drops that emerged later, and the author believes that this interval of time was sufficient for a notable degree of dilution of the blood to take place through the entry into the capillaries of lymph in consequence of sudden vasodilatation. He points out that owing to this possibility the results of blood counts made in highly nervous individuals must be accepted with caution.

Experimental Tabes in Dogs.—Spielmeyer describes lesions he was able to produce in dogs by inoculating them with the trypanosomes of sleeping sickness. In the course of his experiments he found that most of the lower animals could not be used because they succumbed to the infection long before demonstrable lesions of the nervous system had been caused, and even with the dogs it was difficult to keep the animals alive long enough to obtain satisfactory specimens. In seven instances, however, he was able to demonstrate, by means of the Marchi method, degeneration of the posterior root tracts in the cervical region of the cord, of the sensory root of the trigeminal nerve, and, in two cases, of the optic nerve. While the clinical symptoms attending this degenerative process of the central nervous system were not those of tabes, the anatomical changes were so pronounced that the author considers it justifiable to speak of the condition under this name, and he compares the condition with the post-syphilitic tabes of man.

The Opium Bromide Treatment of Epilepsy.—Kellner considers that by combining the use of opium and baths with the bromides better results are obtained in the treatment of epilepsy than by the resort to bromides alone. Out of eighty patients treated according to the plan to be detailed, complete freedom from attacks during a period of from two to six years was obtained in 27.5 per cent., great improvement in 16 per cent., diminution in the frequency and severity of the seizures in 29 per cent., and in the others the treatment was either without effect or had to be abandoned. The treatment is as follows: During the period of fifty days the patient is given three times a day extract of opium, beginning with a dose of 0.05 g. and increasing every other day by 0.01 g., so that by the fiftieth day the highest dose of 0.29 g. is reached. On the morning of the fifty-first day a maximum dose of 0.3 g. is given, and this concludes the opium treatment. Bromides are now given as follows: at noon and in the evening of the fifty-first day 2 g. are given of a bromide mixture containing one part each of bromide of potassium and bromide of sodium, and half a part of bromide of ammonium. On the fifty-second and fifty-third days 6 g. of this mixture are given, on the next two days 7 g., on the next two days 8 g., and from the fifty-eighth day on 9 g. during a long period of time. During the opium treatment the patient takes three times a day a tablespoonful of 1 per cent. hydrochloric acid solution, and Carlsbad salt as needed. The third factor in the treatment is the use of baths, which are taken daily during the opium period. On the first day the bath has a temperature of 24° C. and lasts ten minutes, on the second day 23° and lasts 9 minutes, on the third day 22° and lasts 8 minutes, and so on until on the eighth day it has the temperature of 17° and lasts 3 minutes. This is continued until the fifteenth day, and then from the sixteenth to the twenty-third day the bath lasts 4 minutes, from the twenty-fourth to the thirty-first day 5 minutes, and from the thirty-second to the fiftieth day it lasts six minutes. In addition, the usual hygienic régime, comprising abundance of fresh air, suitable physical employment, diet, etc., is insisted on. The author subjects to this treatment only such patients as are physically well enough to stand the opium dosage, and whose mentality is sufficiently well preserved to make a return to the normal condition seem possible.

Deutsche medizinische Wochenschrift, November 22 and 29, 1906.

The Influence of Radiography on the Treatment of Fractures.—König says that one drawback which has attended the universal use of the *x*-ray as a diagnostic measure in cases of fracture has been the fact that at present there is a tendency for practitioners and students to consider that the thorough study of the subject of fractures, which was formerly requisite in order to make accurate diagnosis and correct treatment possible, is now no longer necessary since a brief examination with the rays will furnish all the information desired. König believes that this is a mistaken point of view, and states that in his clinic he requires his assistants and students to make every diagnosis as carefully and fully as possible before resorting to radiography. By this system the surgeon profits to an extreme degree, and soon acquires the ability to recognize minute alterations in contour, form, etc., that previously would have escaped his attention. For certain classes of fractures, such as simple breaks in the shafts of the long bones, the use of the *x*-ray is not absolutely necessary, and the failure to employ it does not lay the surgeon open to criticism. On the other hand, in all cases in which joints are involved, or in which any doubt as to the nature of the injury can exist, it is malpractice not to make use of the assistance afforded by the Roentgen ray. Through the application of the rays our knowledge of the pathological anatomy and the mechanics of fractures has been greatly amplified, and several types of fracture have been discovered which formerly were not recognized at all. In many instances the surgeon is by this means enabled to secure data which indicate the necessity for and the best means of performing operative procedures.

The Examination of the Blood and Tissues in Cases of Syphilis.—Neisser, Bruck, and Schucht describe a very intricate series of reactions used by them in order to determine whether extracts of organs or body fluids obtained from supposably syphilitic human beings or monkeys contain either the antigen or antibody of the disease. The reaction is essentially founded on the principle of the deviation of the complement, but as the authors themselves point out, it is still too complicated to be available for use by any but the most experienced investigators. They believe, however, that it promises well for the future as a clinical method, and that it is already possible to determine whether a remote syphilitic infection has been cured or is still present as a latent condition. As the result of over 200 experiments on human beings, and a very large series of observations on animals, the authors come to the conclusion that in cases in which the antigen reaction is positive antisyphilitic treatment should always be instituted. On the other hand, if no antigen can be demonstrated but the antibody reaction is positive, treatment is necessary only if the patient never has had antisyphilitic treatment, or if more or less indeterminate but suspicious symptoms are present. Negative reactions, it appears so far, are not to be considered as controverting the clinical diagnosis, and a negative reaction does not yet have sufficient weight in the authors' opinion to warrant the omission of syphilitic treatment if this would appear advisable from the clinical manifestations. It is desirable to repeat the tests at intervals of several weeks in negative cases, as it has been found that the antigen is variable in its appearance and may disappear for a time, only to reappear again later. An interesting part of the investigations is concerned with the examination of the blood and cerebrospinal fluid in cases of tabes, but the results obtained are not conclusive.

French and Italian Journals.

Pellagra.—According to M. B. Triller, who has written a thesis on this subject, pellagra may develop at any age. Women are more susceptible than men, especially between the ages of twenty and forty years. The disease is more frequent during the hot season, due doubtless to the increase in the toxic power of the injurious constituent of the maize. The characteristic erythema is aggravated or even caused by sunlight, although it may occur independent of this action. Alcohol acts strongly as a predisposing cause by its debilitating effect on the patient. The most marked lesions are those of the central nervous system. The lesions of the peripheral nerves are far less important and are probably secondary to those of the central nerve cells. The intestinal mucosa is generally atrophied. The cutaneous lesions have nothing characteristic about them. Not much study has been given to the condition of the blood. The disease may be divided into three stages. The diagnosis is generally easy in places in which pellagra is endemic. The prognosis is ordinarily grave. Recovery has never been observed after the third stage has been reached. The treatment of the disease is practically prophylactic. Maize should not be eaten, or it should not be allowed to become toxic, otherwise the treatment is purely symptomatic.—*La Tribune Médicale*, September 22, 1906.

Appendicitis Consecutive to Enteritis of Infancy.—Aug. Broca declares that in the greater number of cases an attack of acute febrile appendicitis shows itself in peritoneal symptoms. It is well known that constipation is one of the most ordinary symptoms of peritonitis. Appendicular peritonitis, severe or slight, follows this rule, and in crises of this nature obstinate constipation is habitual. However, diarrhea is probably more frequent than is generally believed. The writer calls attention to the septic diarrheas which occur when peritoneal or general infection is already clearly marked; he also makes allusion to those attacks which precede by some days symptoms by which appendicitis reveals itself; and to those attacks which together with vomiting mark the beginning of a crisis, sometimes continuing a short while and sometimes ceasing, giving place to constipation due to peritoneal reaction. The writer's observations show that in the midst of an attack of mucomembranous enterocolitis of the most chronic type and distinctly characteristic there may develop an appendicitis of the most serious form which may terminate fatally. As to the frequency with which this happens, Guinon has observed 20.7 per cent. cases of appendicitis in various forms of enterocolitis among children. The writer considers this a minimum estimate.—*Société de Chirurgie de Paris*, 1906.

Intestinal Occlusion.—H. Roger and M. Garnier state that the occurrence of intestinal occlusion is sometimes due to a reflex action, sometimes to an intoxication of the organism, and sometimes to an infection by intestinal microbes. The writers have conducted various experiments on the ground of the toxic theory as well as in relation to the theory of infection. It seems difficult to attribute to the common bacteria and to those slightly virulent the genesis of the phenomena which have been observed. As to the reflex theory, it scarcely lends itself to experimental researches. Facts prove, nevertheless, that the structure of the intestine and mechanical distention are incapable of causing any appreciable trouble. The toxic theory is the only one which is scientifically admissible.—*Revue Française de Médecine et de Chirurgie,* October 10, 1906.

Sweating Sickness and the Rat.—Chantemesse, Marchoux, and Havry have made a study of an epidemic of sweating sickness which occurred in May and June in the department of Charente. Within six weeks 6,000 people were attacked by the disease. The epidemic occurred especially in the villages. Blood examination and examination of the cerebrospinal liquid have not led to the discovery of any germ which could be inoculated and cultivated. This sickness seemed to propagate itself only where there were bridges. In character it was far more epidemic than contagious. Women are more susceptible than men, especially those that live in houses without floors. When there is an outbreak in a village it is the houses in the outskirts whose inhabitants are first infected. In view of these facts Chantemesse suggests that the rats and fleas may be the carriers of this disease. It is merely an hypothesis, but merits attention. The region invaded by the sweating sickness is exactly that which two years ago was overrun by meadow mice. Besides this the patients examined by Chantemesse showed numerous marks of flea bites. —*Gazette des Hôpitaux Civils et Militaires,* October 25, 1906.

Acquired Hemihypertrophy of the Face.—Fabio Rivalta finds in literature twenty-three cases of hemihypertrophy of the face, of which seventeen were congenital and only five acquired. To these he adds one acquired case observed by himself. This condition is exceedingly rare, especially in the acquired form. The patient observed by the author had a neuropathic heredity. His hypertrophy was left-sided and began at the age of fifteen years, progressing very slowly up to his thirty-third year, when it began to increase rapidly until the one-sidedness of the face was very marked. It involved the lower maxilla alone, with no increase of the soft parts. After a careful examination of the other five cases recorded and of the history of this case, the author gives us these conclusions as to the etiology of the affection: It is probably of central nervous origin; it is due to the trophic disturbances, trophic fibers being carried to the bone in the trigeminus; there is produced an increase of trophic function by some irritation of the nerve. The author's case had a lesion of sensibility in the trigeminus of the same side.—*Il Policlinico,* September, 1906.

Cancroprecipitins and Their Application to the Early Diagnosis of Gastric Carcinoma.—Dario Maragliano says that this method of diagnosis by cancer precipitins depends on two biochemical facts: first, that in the reaction of precipitation it is the immune serum that is precipitated by the albuminoid solution that has been used for immunization; second, that immune serum contains as many sorts of precipitable substances as there are precipitating substances injected, that is, the serum is polyvalent. Hence it is possible to precipitate and isolate from the immune serum the different precipitating substances and to remove them. Animals are immunized with the fluids derived from a stomach that is the subject of carcinoma, and their serum is then made to react with the gastric juice of the suspected patient. The author has obtained a serum that reacts to cancerous gastric juice, but does not react to the normal blood serum. With the juice of normal stomachs it does not react at all, but that of a cancerous stomach causes precipitation. The carcinomatous gastric juice precipitates the immune serum by the presence of special albuminoids of a cancerous nature independent of the albuminoids contained in the juice itself. He believes that this reaction should be tried in all suspected cases of cancer as the Widal reaction is used in typhoid. He has tested seventeen cases of stomach disease, and found the reaction positive in twelve of them, and in all these cases operation or autopsy showed that there was cancer of the stomach present.—*La Riforma Medica,* August 18, 1906.

Heredity as a Factor in Infantile Eclampsia.—Walfredo Chiodi says that, given the small resisting capacity of the infant, due in part to lack of development and in part to incomplete adaptation to his surroundings, slight stimuli will produce great nervous disturbances. He considers of great importance the stimuli which act on the child, but still more important is the ability to resist them, and that is supremely affected by the heredity of the child. All forms of neurotic conditions, not only of the parents, but also of the ancestors, affect this power of resistance. Whatever nervous disease exists in the ancestors may be transmitted in an entirely different form to the descendant, predisposing him to convulsions. Convulsions are found to appear in children of hysterical, epileptic, and eclamptic mothers, while the use of alcohol by the parents has a marked tendency to be transmitted to the child as a tendency to eclampsia in infancy.—*Giornale Internazionale delle Scienze Mediche,* August 15, 1906.

Sarcoma of the Labium Majus.—Siegel, Dalval, and Marie report this case. The tumor was removed by Riche from a woman forty-three years old. The patient had noticed the growth for the first time ten years before. Previous to this time she had always enjoyed good health. The growth first appeared as a small, hard, painless tumor, which increased in volume slowly without ever showing any inflammatory reaction. At the end of three years the tumor was extirpated. For about three years there was no recurrence. Then the tumor reappeared with the same characteristics that it presented in the first place. It grew to the size of a small orange. It was movable upon the tissues underneath. The skin covering it was thin, very adherent, of a violet color, dotted here and there by whitish spots due to small protuberances on the surface of the tumor. There was no ganglionic involvement. Histological examination showed that the tumor was sarcomatous in type, consisting of generally atypical cells.—*Bulletins et Mémoires de la Société Anatomique de Paris,* May, 1906.

Cysts of the Cerebral Apophysis.—Alessio Nazari reports two cases of cyst of the apophysis occurring in adults, in neither of which were they diagnosticated during life, owing to an entire absence of symptoms that might be referred to the organ. The literature of this form of tumor is very small in amount, very few cases having come to autopsy. In one of the author's cases there was present a tumor of the temporosphenoidal lobe of a gliosarcomatous nature, and the cyst of the apophysis was not suspected. In the other there was chronic pulmonary tuberculosis, tuberculous meningitis, infantilismus, persistent thymus, and hypoplasia of the thyroid gland. Here the tumor of the apophysis was of considerable size, four and one-half by three centimeters in diameter. The cysts were cholesteatomatous in nature, as was shown by the contents. The investing membrane was formed by a connective tissue membrane lined with a single layer of epithelial cells, not cylindrical or vibratile.—*Il Policlinico,* October, 1906.

Diagnostic and Therapeutic Value of Lumbar Puncture in Epidemic Cerebrospinal Meningitis.—Arturo Primavera gives the histories of four cases of epidemic cerebrospinal meningitis treated by him by lumbar puncture, and records his conclusions. There is no doubt of the therapeutic value of lumbar puncture in this disease. It should be made at the very beginning of the disease to get the best results, before anatomical lesions have taken place that prevent cure. The value of this procedure is not merely symptomatic or palliative, but is far wider. Extraction of fluid calms the nervous symptoms, relieves pain, diminishes cerebral tension, lessens the toxic condition of the cerebrospinal fluid, and helps the organism and the nervous system to react against the disease. It is of great value in assisting diagnosis by showing the presence of polynucleosis, which serves to distinguish it from the chronic inflammatory form of meningitis.—*Giornale Internazionale delle Scienze Mediche,* October 15, 1906.

Recurrences in Diphtheria.—Gino Menabuoni finds that in the Pediatric Clinic at Florence, from 1892 to the present day, there have been 2,300 cases of diphtheria treated, with 39 recurrences among them, all confirmed bacteriologically; that is, one and seven-tenths per cent. The author limits the term recurrence to cases of new infection, in which a considerable interval has elapsed since the preceding attack, and in which it has been ascertained that the bacilli were absent from the throat in the interval. Children are not allowed to leave the hospital until a clear culture has been obtained. The bacillus remains in the pharynx usually for from one to thirty days after the disappearance of the membrane. Among predisposing causes the author mentions the anatomical condition of the pharyngeal mucous membrane; the existence of other infectious diseases, such as scarlatina, and the presence of some milder form of respiratory infection. In general the second attack is much milder than the first one. Out of the thirty-nine cases there were three deaths, one from asphyxia, one in a case complicated with scarlatina, one with measles. Probably the mildness is due to a resistance of the organism to the poison, and not to a mild type of infection.—*Rivista di Clinica Pediatrica,* October, 1906.

Book Reviews.

THE DYNAMICS OF LIVING MATTER. By JACQUES LOEB, Professor of Physiology in the University of California, Columbia University Biological Series VIII. New York: The Columbia University Press, The Macmillan Company, Agents. London: Macmillan & Co., Ltd., 1906.

As is well known, Professor Loeb is the advocate of a robust optimism which regards experimental abiogenesis as the objective point of biological research and presses forward to this goal with an ardor that makes success seem rather more than a possibility. The present volume is founded on the series of lectures given by the author four years ago at Columbia University, though these have been amplified and broadened in scope so that the book represents a well-rounded exposition of the most recent work in experimental biology. After an introductory discussion of the modern notions of the mechanism of heredity and evolution, in which considerable prominence is accorded De Vries' postulate of the mutation of species by jumps, the following subjects are treated: The general chemistry of life phenomena; the general physical constitution of living matter; some physical manifestations of life; the rôle of electrolysis in the formation and preservation of living matter; the effects of heat and radiant energy on living matter; heliotropism; tropisms and allied phenomena; fertilization; heredity; the dynamics of regenerative processes. While, naturally enough, some portions of the book are of a nature to appeal particularly to laboratory workers, others should prove of great interest and value also to the general medical reader. Such, for example is the exposition of the considerations relating to the determination of sex, which lead the author to the conclusion that sex is, in all probability, already predetermined in the sex cells. The matter of regeneration is a subject fraught with practical possibilities, and the discussion of the effects of heat and radiant energy on the living cell also has a medical application. The work is an important contribution to a fascinating subject, and it may well be commended to the physician desirous of following the progress made in the sciences allied to medicine.

EATING TO LIVE, with Some Advice to the Gouty, the Rheumatic, and the Diabetic. A Book for Everybody. By JOHN JANVIER BLACK, M.D., Member of the College of Physicians of Philadelphia; Member of the Delaware State Medical Society; Author of "Forty Years in the Medical Profession," "Cultivation of the Peach, Pear, Quince, and Nut-Bearing Trees," etc. Philadelphia and London: J. B. Lippincott Company, 1906.

THE author in his preface likens human beings in their habits of eating and drinking to sheep, which have not the slightest idea of taking care of themselves. Many interesting problems such as personal idiosyncrasy are considered. The horrors of the quick lunch, the modern lunch, full late dinner, and heavy supper after the opera are all held up for criticism. There are various charts which make the text more graphic. In these are shown the average composition of common American food products; coefficients of digestibility and fuel values per pound of nutrients in different groups of food materials; composition of food materials, nutritive ingredients, refuse, and fuel values; food consumption of persons in different circumstances, and proposed dietary standards; pecuniary economy of food, amounts of actually nutritive ingredients obtained in different food materials for ten cents; comparative cost of digestible nutrients and energy in different food materials at average prices. Special diets for the conditions of corpulence and leanness, as well as for various diseases, are discussed. The characteristics of different kinds of food, including beverages, are given. There is a good index. The volume is helpful and interesting, but would be greatly improved as a book of reference if the text was arranged in chapters.

A TEXTBOOK ON THE PRACTICE OF GYNECOLOGY, for Practitioners and Students. By WILLIAM EASTERLY ASHTON, M.D., LL.D., Fellow of the American Gynecological Society; Professor of Gynecology in the Medico-Chirurgical College, and Gynecologist to the Medico-Chirurgical Hospital, Philadelphia; Formerly Lecturer in Gynecology in the Jefferson Medical College, Philadelphia; One of the Founders of the Congrès International de Gynécologie et d'Obstétrique; Member of the American Medical Association. With Ten Hundred and Fifty-seven New Line Drawings Illustrating the Text by JOHN V. ALTENEDER. Third Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1906.

THERE are two things doubtless that have won for this work such favor with students and practitioners as to demand a third edition within fifteen months after the original publication; these are the clear, direct style in which the author presents his subject and the excellence of the illustrations. The work is especially adapted for students' use by reason of the systematic arrangement of subjects and of the free use of side heads in heavy type facilitating ready reference and aiding memory.

After a number of preliminary chapters on the General Technique of Gynecological Examinations, Microscopical and Bacteriological Examinations, the Blood in Relation to Surgery, Hydrotherapy, Diet, Saline Injections, History Taking, the Causes of Diseases Peculiar to Women, etc., the discussion of the diseases of the various organs is taken up in anatomical order. This arrangement, though arbitrary and not always consistent, has the advantage that it permits a discussion of the methods of examining each organ before describing its diseases, and so does away with the necessity of a special chapter on physical examination, which, the author thinks, tends to confuse the student by reason of its broad generalization.

In this new edition certain changes have been made to conform to a change of views which the author's personal experience has led him to adopt, so that the book represents Dr. Ashton's "views at the present time, based upon an actual working knowledge of the advances that have been made in gynecology and abdominal surgery." This personal note adds greatly to the value of the treatise. The book is inordinately large—nearly 1,100 pages—and correspondingly heavy. It would, we think, have been wiser, certainly more kind to the reader, to publish the work in two volumes, even at the expense of an increase in price. A textbook should be literally a manual, a book that can be held in the hand when it is read, and not one that calls imperatively for a desk or some sort of book-rest. However, the road to knowledge is proverbially difficult, and the meat that is to be gotten out of this excellent work is worth the labor of getting it. The illustrations are numerous and most instructive.

A TEXTBOOK OF HUMAN PHYSIOLOGY. By ROBERT TIGERSTEDT, Professor of Physiology in the University of Helsingfors, Finland. Translated from the Third German Edition and Edited by JOHN R. MURLIN, A.M., Ph.D., Assistant Professor of Physiology in the University and Bellevue Hospital Medical College, New York City. With an Introduction by Professor GRAHAM LUSK, Ph.D., F.R.S. (Edinb.). New York and London: D. Appleton & Co., 1906.

IN presenting an English version of Professor Tigerstedt's textbook the translator has incurred the gratitude of all students of this subject who are unable to read the original. The work is one of those most widely used in the Continental universities, and is even supplanting the beloved Hermann's Lehrbuch der Physiologie which has so long been a universal favorite. No doubt it will meet with the same approbation in this country. Tigerstedt is at his best in the discussions of the general principles of physiology as related to biology as a whole, of the circulation, of metabolism, and of the nervous system, and these topics are treated in masterly fashion. The one subject which receives rather less space than it would seem to deserve is digestion, though this is perhaps due in large measure to the fact that the author has made it a point to omit as much as possible the more intricate chemical considerations that now constitute so formidable a problem for the advanced student. The work of translating and editing has been performed with praiseworthy skill and discretion. The English is excellent and has no Teutonic flavor, while Professor Murlin's decision to omit some of the more highly technical parts of the book, such as the mathematical considerations relating to the optics of vision and the mechanics of the circulation, is only to be commended. The editorial emendations are apt, and, like the illustrations that have been added, serve to enhance the value of the work for American readers. To borrow the phrase with which Professor Lusk closes his introduction to this edition: "The book may be earnestly commended to the medical student and to the practitioner."

TRAITÉ DES MALADIES DU NEZ. Par le Docteur A. Ménier, Ex-Interne des Hôpitaux de Paris, etc.; Introduction de M. le Professeur S. DUPLAY; Preface de M. le Docteur A. CASTEX. Paris: A. Maloine, 1906.

OF making many books there seems to be no end, especially in rhinology, and our Gallic friends seem determined to keep up with the procession. The present volume is an exhaustive exposition of diseases of the nose and goes somewhat more deeply into the general and plastic surgery of this organ than is usual with works of its class. It is well printed on good paper, but some of the illustrations are very poorly executed. One commendable feature is an index of authors referred to. The general index is complete. The chapters on nasal deformities, vestibular dermatoses, and tumors are unusually elaborate.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GYNECOLOGY AND OBSTETRICS.

Stated Meeting, Held November 22, 1906.

DR. HERMANN J. BOLDT, CHAIRMAN PRO TEM.

Large Multilocular Ovarian Cyst in a Woman Over Seventy Years Old.—Dr. L. J. LADINSKI presented this specimen which he removed from a woman, 70 years old, who had been married 50 years and had had eight children, the youngest being 30 years. She had never had an abortion and all her labors were uncomplicated. She began to menstruate in her thirteenth year, and menstruation ceased in her fortieth year. Her family history was negative. For the past three years the patient had an abdomen moderately enlarged, but she complained of nothing except occasional stinging pain in the middle of the lower abdomen. In the past year the patient had a ventral hernia kept reduced by a truss, and which never caused any pain. There were no gastric disturbances, and no edema of the extremities. During the past two months the patient's abdomen had gradually and markedly enlarged until it became the size of a full term pregnancy, causing a feeling of extreme distention of the abdomen, and pain which was referred to the left side. Discomfort due to distention was felt par ticularly at the side of the abdomen, and in the past two months it had been impossible for the patient to recline on the left side. The urine had been diminished in quantity and had been voided every one or two hours without pain. Her bowels were regular and her appetite was poor. There was no loss of flesh, but there was of strength. On admission her temperature was 99.6°, pulse 108, respiration 30. Examination of the urine was negative. Hemoglobin was 60 per cent,, leucocytes 9,000, polynuclears 62 per cent., small mononuclears 16.5 per cent., large 16.5 per cent., eosinophiles 4 per cent, and transitionals 0.5 per cent. The abdomen was extremely distended by a tense irregular and nodular tumor. There was flatness over the entire abdomen except in region of umbilicus which presented a large hernia. There were no signs present of superficial or deep fluctuation or of free fluid in the peritoneal cavity. Vaginal examination revealed a very small uterus and a hard, immovable mass high up in the pelvis. No positive diagnosis was made and an exploratory laparotomy was advised. A median incision was made from just below the umbilicus which was displaced considerably upward to within 2 inches of the symphysis, encountering considerable venous bleeding. On opening the peritoneum a small amount of blood-stained serum escaped. A large cystic tumor was found, extending in all directions, filling the abdominal cavity, and thoroughly adherent to parietal peritoneum and intestinal coils. The incision was extended upward in the median line, the umbilicus being deviated to the left, and the upper part of the tumor was separated from dense adhesions with transverse mesocolon and intestinal coils. The entire sac of the tumor was bound down by adhesions to the surrounding parts, and by breaking up some of the adhesions and tying others the tumor was finally freed. Several large and small cysts were broken into which discharged dark-brown fluid containing gelatinous matter. The tumor was delivered, and the pedicle which sprang from the right broad ligament was clamped, ligated, and cut. Bleeding from separated adhesions was very profuse, especially in the upper part of the abdomen and from the transverse mesocolon, but was controlled by packing with very hot towels. An internal hernia was present, but it was not thought advisible to prolong the operation to cure the same. The abdominal wall was sutured in layers, using No. 1 iodine catgut for the peritoneum continuously, No. 2 interrupted sutures for muscle, and No. 2 chromic continuous for the fascia, and No. 1 iodine continuously for the skin. Subsequent to the operation the temperature ranged between 99° and 100° until discharged, although it was slightly above the latter figure for twenty-four hours after the operation. The pulse ran between 100 and 110 until the second week, when an average of 85 was reached and maintained. The respirations were normal. Her bowels were moved by calomel, salts, and enema twenty-four hours after the operation and spontaneously after the second day. There was primary union in the wound and convalescence was uncomplicated. The patient sat up in bed on the twelfth day, and was out of bed on the fifteenth day. She was discharged, cured, on the twenty-second day after the operation.

Fibrocyst of the Left Ovary, With Ventral Hernia, Complicating Pregnancy.—Dr. LADINSKI presented this specimen, which he had removed from a woman, aged 35 years, and who had been married fifteen years. She had had six children, the eldest being 12 years, and the youngest 5. Menstruation began at the age of 18, was normal in type, her last menstrual period occurring three months ago. Her family and previous histories were negative. Her present trouble dated back to her first childbirth, twelve years ago, when, after a prolonged labor, a large ventral hernia followed. This gradually increased in size, and during pregnancies would contain the uterus, becoming larger after each labor, none of which since the first had been spontaneous. During the past few months she complained of pain all over the lower abdomen, sticking in character. Her last menstruation was three months ago, and at present she felt an enlarged uterus in the hernia hanging down over the symphysis. She was constipated, but urination was normal. There was no edema of the extremities. On admission to the hospital her temperature was 99°, pulse 120, respirations 28. Physical examination showed relaxed abdominal walls, marked diastasis of the recti, and protrusion of abdominal contents into abdominal wall. Vaginal examination revealed a pregnant uterus of the third month, and a cystic tender mass, the size of a fist, freely movable in the left pelvis. The urine showed a faint trace of albumen, but no casts. A Pfannenstiel Stimson incision was made with its convexity downward and the other layers of the abdominal wall below the subcutaneous tissue were divided longitudinally. The left ovary was found to be enlarged by a fibrocyst; the cyst was distinctly pedunculated. The pedicle was transfixed, tied, and the tumor removed. The peritoneum was separated on either side of the incision and an attempt was made to bring it together by continuous suture; this was, however, abandoned after closing one-third of the wound because of the friability of the tissues. The interrupted sutures were left untied until the recti muscles were approximated by interrupted sutures, the peritoneal sutures being tied as muscle suturing advanced. The anterior layers of the sheaths of the recti were separated, and the left flap was made to overlap the right by mattrass sutures, and its free border united well over on the right side by continuous suture.

Hysterectomy for Placental Polyp.—Dr. LADINSKI reported the case of a woman, 35 years old, married eighteen years, the mother of five children, the last one six years ago. Since the birth of the last child she complained vaguely of not feeling well, and had had attacks of stabbing pain in the lower abdomen on both sides, at intervals of one to three months, these attacks being usually accompanied by slight fever, but with no chills. She complained acutely during the past five months. Up to this time the menses had been regular in occurrence, but profuse, lasting a week or more, and followed by a leucorrheal discharge. In the past four months, after an amenorrhea for two months, bleeding had been continuous, varying in amount from day to day, sometimes profuse with pieces of clotted blood. The pain in the lower abdomen was more acute and constant for a period of three weeks, two months ago, when she was curetted by her attending physician. She felt

improved as regards the pain, but it was without effect on the bleeding. On admission to the hospital the temperature was 100.2°, pulse 92, respiration 26. Examination of the urine was negative. The leucocytes numbered 10,600, polynuclears 62.5 per cent., small mononuclears 20 per cent., large mononuclears 14.5 per cent., transitionals 2 per cent., and eosinophiles 1 per cent. The patient was very anemic. Examination revealed cystic degeneration of both ovaries and the uterus was somewhat enlarged but normal in contour and baggy in consistency. The cervix was normal and the external os was contracted. A diagnosis of possible deciduoma malignum was made and an immediate operation was advised. The uterine cavity was curetted and swabbed with carbolic and alcohol. The external os was closed by a number of sutures. A circular incision was made in the cervical mucosa; the posterior cul-de-sac was opened and the anterior peritoneal reflection incised after lifting up the bladder. The patient was placed in the Trendelenburg position, and an incision made in the median line of the abdomen, below the umbilicus. The pelvic organs were exposed, the uterus drawn upward, the ovarian vessels ligated with catgut, and the broad ligament was severed down to the uterine arteries. The vaginal mucosa, previously separated, was pulled up and the edges brought together by interrupted and continuous sutures. The abdominal wall was closed and primary healing followed. The patient was out of bed on the eighteenth day and discharged, cured, on the twentieth day after admission.

Early Cornual Pregnancy.—Dr. Ladinski reported the case of a woman, married twelve years, the mother of two children, the last having been born seven years ago. She always had been in perfect health. While in the mountains she was suddenly taken at 5 A. M. with pain in the abdomen and entered into collapse. The case was diagnosed as extrauterine pregnancy. Dr. Ladinski was telephoned for and arrived on the afternoon of the same day. Her condition was then bad, but it improved. He made a diagnosis of internal hemorrhage, but he could not make the diagnosis of extrauterine pregnancy. It proved to be a case of isthmeal pregnancy. Examination under an anesthetic did not enable him to make a diagnosis because there was no tumor. The specimen was shown.

Four Cases of Cesarean Section.—Dr. S. W. Bandler reported these cases.

Case I.—This was a case of vaginal cesarean section for placenta prævia centralis with profuse hemorrhage at six and a half months. When sent into the hospital the patient was very anemic, pulse 120 and temperature 101°. A transverse incision was made on the anterior wall of the cervix and the bladder was dissected off from the anterior uterine wall. A transverse incision was then made on the posterior wall of the cervix with dissection up to the sac of Douglas. A median splitting of the cervix, anterior and posterior, was made up to the internal os, or lower uterine segment, without invading the peritoneum. The hand was introduced, the gestation sac was ruptured, and the fetus was removed by the legs, the membranes and placenta being removed manually. Another fetus and sac were found in the uterus and these were removed by the same procedure. Hot lysol douches were given and the uterus was packed with gauze. The cervix was sewn with six chromic sutures anteriorly and four posteriorly. The transverse vaginal incisions were also closed. The patient ran a high temperature for two weeks, which was controlled by intrauterine lysol douches and ergotole. Recovery followed.

Case II.—The patient was a multipara, pregnant at the eighth month. A large ventral hernia followed an operation for appendicitis. There was a very extensive ulceration of the skin over the hernial protrusion, due to intra-abdominal pressure. The cervix and lower uterine segment were packed with gauze; this packing was increased after two days. The cervix was then long and dilated only to two fingers. The uterus was atonic and a vaginal cesarean section was decided upon. The fetus was extracted and the placenta and membranes were removed manually. Hot antiseptic intrauterine douches were given and the uterus was packed with gauze. Ergotole was given hypodermically. A rapid convalescence occurred.

Case III.—This was a case of hyperemesis gravidarum. The patient was pregnant ten weeks. There was constant vomiting in spite of saline enemata. The temperature was 100°, and the pulse 100. The sensorium was benumbed. There was an acute retroflexion and a long narrow cervix. After proceeding as in Case I the middle finger was passed into the uterus, and, with the aid of the external hand, the ovum was completely peeled off from its uterine connections. The complete ovum was removed with the placental forceps. Intrauterine hot douches of lysol were given and the uterus was packed with gauze. A rapid convalescence followed.

Case IV.—The patient was a II-para and pregnant ten weeks. In her previous pregnancy albumin and casts appeared in the urine. There was a high general edema. In the present pregnancy albumin and casts were present. A minor vaginal cesarean section was performed and the ovum was removed complete by the middle finger *in utero*, aided by the external hand, as in Case III. Hot intrauterine lysol douches were given and the uterus was packed with gauze. Ergotole was given hypodermically. The anterior and posterior incision in the cervix were closed with chromic sutures and the vaginal incisions were also closed. Intrauterine gauze packings were introduced.

The Value of the Differential Leucocyte Count in Gynecology and Abdominal Surgery.—Dr. Frederic E. Sondern opened this discussion. (See page 989.)

Dr. Norman Edward Ditman said that he could not impress too firmly upon the minds of his hearers that surgical, gynecological, and medical leucocytosis were three very different things, and it was undoubtedly due to this little-recognized fact that so much discussion on this subject had been created. In the average surgical case the interpretation of the leucocyte count admitted of very little chance for error, realizing the usual influence of bodily resistance and virulence of the organism. It was only necessary to remind them of how the low counts and polynuclear percentages due to excessive virulence and diminished resistance might be altered by complicating conditions, as illustrated by the fact that a starving man might have as few as 861 leucocytes (Succi) and some conditions as few as 3 per cent. polynuclears. The latter occurred in a case of lymphatic leukemia and was most interesting when one remembered that inflammatory processes caused a diminution in the number of leucocytes in this condition. The leucocyte count in ordinary surgery ran almost with the regularity of clock work, and it was comparatively easy to sit down near a book of bedside notes, or in the laboratory, and make rules which would apply in most cases. Such was true also, to a large extent, in gynecology, although the counts in this branch did not bear so well the tests of the modern refinements of classification. The most marked and uniform response in gynecology was in conditions of pelvic abscess. While pus under pressure usually gave very high counts, in inflammatory conditions of the Fallopian tubes and ovaries the leucocytosis was usually of only a moderate degree, with none in the majority of the chronic cases. The early cessation of leucocytosis in these cases was accounted for by the fact that the inflammatory process became walled off, and that the organism which was usually the causative agent, the gonococcus, soon died. To show that his experiences had not been always the same as Dr. Sondern's, he quoted a few cases. The rule that Dr. Gibson launched, for pure surgical work, had far fewer exceptions, and he believed should prove a very useful adjunct to existing methods of surgical diagnosis. He referred to the use of his so-called "standard" scale. After

quoting Dr. Robert N. Wilson's conclusions to his paper on "The Meaning and Significance of Leucocytosis," he said that in a series of gynecological cases examined at Roosevelt Hospital there was some kind of response to inflammation by increase of leucocytes or per cent. of polynuclears, or both, in every case. In 11 per cent. of these cases, however, there was a leucocytosis of some form when no pus was present. The application of Gibson's "standard count" rule to this 11 per cent. would cause inflammation as a cause to be ruled out in all but 2 per cent. Of the gynecological cases where pus was present with high leucocyte count and high per cent. of polynuclears, 24 per cent. were above Gibson's "standard" line and 76 per cent. were exceptions to his rule. Taking into consideration pus cases with the leucocytes normal as well as high, 62 per cent. were exceptions to his rule. A fact he wished particularly to accentuate was that leucocytosis, in diseased conditions was not necessarily a result of infections, but might occur as the result of absorption of a number of chemical substances, some of which were the products of cellular or bacterial activity in or outside the body. After enumerating the conditions which might be confused with surgical inflammatory conditions, as well as those which might occur as complications of surgical conditions which must be taken into consideration at the time of making a diagnosis, he said that if the recently-formulated rules applying to the significance of high leucocyte and polynuclear counts were followed in these cases without due consideration of other factors, a great deal of unnecessary and useless operating would be the result. The great value of repeated counts was emphasized. By this means many of those confusing conditions which he had recited, occurring usually as medical conditions, or complications, might be excluded, as their leucocytoses were of short duration. In connection with the variation in repeated counts, a most important factor was the general condition of the patient, and it was by the heeding of these factors that a prominent surgeon, whom he had observed, had on a number of occasions procured resolution of inflammatory conditions without operating where, but for close observation on these two points in their mutual relationships, operations not indicated would have been performed.

Dr. Charles L. Gibson said that the polymorphonuclear count was of the greatest value, and, as ordinarily made, was fairly reliable, but not when made by a shifting personnel. Dr. Ditman had enumerated many pitfalls; but with him great familiarity with the methods employed gave him greater confidence. There were many things to be taken into consideration, as, for instance, the anesthesia. He presented several charts on which he had tabulated some of his results. He believed it to be better to carry some definite idea in one's mind, and, therefore, he tried to get up a "standard" chart which he considered to be of great value. There were three sets of lines: one running upward, the polynuclear, a rising line, showed some mischief or a lesion badly borne. A slight rise or balance line meant that the process was well borne, or resolving, or diminishing. The descending line meant that they were dealing with a child or infant and the process was of a mild or resolving character. Other interpretations of the lines were given and many charts shown. Some interesting cases were cited. In one a patient entered the hospital with a temperature of 105° and a diagnosis of appendicitis with perforation. Operation was refused. This patient remained under observation for some time. The general process resolved and he left the hospital without losing his appendix. The last observation showed a descending line. He showed another chart with a downward curve. The patient had a temperature of 102°, and a diagnosis of a gangrenous appendix, and here he noted an exception, where one could have pus without increase of the polynuclears, the condition being absolutely safe.

Dr. Howard C. Taylor said that the subject of blood count had a great deal of clinical interest to him, and in a large experience in abdominal cases the blood count was made, both total and differential, and there was no question in his mind as to its value. The point Dr. Ditman and others had made, that there was little value to be attached to a single count, he agreed with. A temperature of 103° in itself did not mean anything, but a temperature of 103° meant something when considered with the blood count. If one studied the temperature curve for hours or days in conjunction with other symptoms it would be of value. There was no doubt but the blood count was of great value when considered with other symptoms. There were pitfalls to be encountered, but the same was true of other signs and symptoms. Typhoid fever might run a typical course, and again it might run an atypical one. This was true of blood counts. In considering gynecological cases he said that an ovarian cyst was not necessarily accompanied by leucocytosis; but it was found when there were certain complications, as from a twist of the pedicle and irritation of the peritoneum, then we would get a leucocytosis without the presence of pus. In later stages the collection of pus might be shut in by a thickened wall; then we got no absorption and no leucocytosis. The leucocyte count in fibroids was interesting; in simple, uncomplicated fibroids one got no leucocytosis; but when the fibroids underwent changes, or became gangrenous, then one got a leucocytosis. He had in mind a patient with a count of 7,000. For one week before operation, without any change in the temperature or pulse, the leucocytosis was 15,000. At operation there was found a small fibroid, two inches in diameter, but gangrenous. One rarely had in fibroids sudden hemorrhage severe enough to cause a posthemorrhagic leucocytosis. The hemorrhage in fibroids was usually a slow and prolonged one, extending over weeks and months. With regard to ectopic pregnancy, if unruptured there was no leucocytosis; but if ruptured there might be a marked leucocytic count. He had had one case with polynuclears 89 per cent. and over, the total count being 30,000. Dr. Brewer had another such a case, the polynuclears having been 95 per cent., the total count 40,000 and over. In both these cases the abdomen was filled with blood. If the blood should become encapsulated four or five days after the hemorrhage the leucocytosis would rapidly diminish. In pyosalpinx of acute form there was a certain increase in the total count, and in the differential; in old cases, with the collection of pus encapsulated, both the total and differential counts would be practically normal. If the condition was acute, with a certain amount of exudate and absorption, one might find an increase in the total and differential counts.

Dr. W. Travis Gibb said he was recently called in consultation to see a woman, 24 years old, who had a temperature of 102°, and with all the symptoms of appendicitis. She was sent to the sanatorium, and by the time she arrived there her temperature was 105°, altogether too high for the amount of symptoms she had. With such a temperature he hesitated about operating. Another gynecologist was called in and advised operation. She had 3,000 leucocytes and 67 per cent. polymorphonuclears. By the time report was made a few typhoid spots appeared. Two months ago he saw a woman with a temperature of 104.5°, with a marked rigidity on the right side. The attending physician made a diagnosis of appendicitis. He confirmed the diagnosis, but added that he thought there was some trouble with the gall-bladder. She was sent to the sanatorium with a temperature of 105°. There were 27,000 leucocytes and 93 per cent. polymorphonuclear cells. Operation was advised. She was pregnant. Her condition became worse and, at operation, the appendix was found acutely inflamed, but without any pus or gangrene. The incision was enlarged and nothing was found in the gall-bladder. The fetus was viable. The appendix was found to be swarming with staphylococci. Immediately after operation the tempera-

ture went down. She aborted on the third day, and the temperature then became normal. In this case the blood count was the guide to operation.

Dr. C. Clarence Sichel said he performed appendectomy for a perforated appendix with localized abscess, and the patient did well for two hours, when the temperature suddenly jumped to 105°. Leucocyte count at that time was in the neighborhood of 20,000, and the polymorphonuclears about 65 or 75 per cent. The wound was found to be clean. This condition of affairs continued for about forty days. At autopsy there was found a small metastatic abscess in the lungs. Throughout the entire course of the disease there had been no marked difference in the leucocyte count, averaging about 25,000, and the polymorphonuclears about 75 per cent.

Dr. Sondern, in answer to Dr. Ditman's statement, said that those figures were not meant to be taken as rules, a fact he distinctly stated at the time he published them. The statement he made at that time was based on cases examined up to that time, numbering about 1,200. The figures given really applied to those cases. If the cases were tabulated now they would give averages different from those given then. So far as a blood examination would take the place of the bedside diagnosis, that was absurd; no diagnosis should ever be made in the laboratory to the exclusion of the bedside findings; laboratory findings were simply aids in diagnosis; such a blood examination was an aid in spite of all the pitfalls and exceptions enumerated.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held November 19, 1906.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Report of the Committee on the Death of Dr. William K. Otis.—By Dr. Robert W. Taylor, Chairman.

Report of the Committee on the Death of Dr. Edward A. Wheeler.—By Dr. Frank C.Raynor, Chairman.

Report of the Committee on the Death of Dr. William P. Brandegee.—By Dr. Edward B. Dench, Chairman.

Morphology a Necessary Factor in the Study of Pathogenic Protozoa.—Professor Gary N. Calkins of the Department of Zoology of Columbia University made a brief address on this subject, illustrating his remarks with lantern demonstrations. He stated there was a growing tendency to drag protozoal research into the somewhat narrow lines of bacteriological technique, and so to limit the normal development of that knowledge. In the determination of an organism, the old-time condition "it must move" seemed to have given place to the more modern one that it "must be cultivated," and in the effort to do that, with the usual outcome of failure, there was some danger that this important field of medical science might be neglected. It was a great achievement to have succeeded in cultivating a protozoon on artificial media, and Dr. Novy and his collaborators were to be congratulated on their results with the flagellate trypanosoma: perhaps, some time, some of the intracellular parasites could be similarly cultivated, but it was not necesary to wait for this before studying them. Professor Calkins showed on the screen a diagram representing the variations in vitality of a free-living protozoon, *Paramecium caudatum*. A single one was isolated in its normal culture habitat, hay infusion, and put into a moist chamber. By the next day it had divided twice. These four organisms were similarly isolated, and four lines of paramecium protoplasm were thus started. On the following day, each of these four had divided, and one from each was similarly selected and isolated as before. In this way the paramecium protoplasm was followed continuously day after day and generation after generation for a period of twenty-three months, or until the protoplasm died from unmistakable protoplasmic old age in the 742 generation. This long period of generations did not represent the normal life cycle of the paramecium, because, owing to the use of artificial stimulants, the vitality was renewed three times, and the 742 generations thus represented four complete life cycles. In any one of these cycles we could trace three well-marked periods of vitality, and each period was characterized by certain peculiarities which could be recognized and by which the stage of the organism in its life cycle could be determined. Thus, there was an initial stage of great reproductive energy, followed by a stage in which the vitality began to wane. It became very plastic, its usually firm and consistent membrane becoming soft and miscible, so that two organisms on coming in contact would fuse. There were also certain nuclear changes by which one could identify this stage in the life cycle. Finally, the last stage was characterized by vacuolar degeneration, gradual breakdown of the cell parts, and death from old age. These three periods in the life cycle of the protozoon, the speaker said, thus simulated the periods of youth, adolescence, and old age in higher animals, and justified his view that the entire cycle and not the single cell should be made the basis of species and genera, and that the whole congerie of cells and not the single one should be regarded as the individual organism. All protozoa passed through similar cycles of vitality, and in all of them it was possible to make out the three periods which were particularly easy to follow in paramecium.

Dr. James Ewing said that while his observations upon the study of pathogenic protozoa were not in close accord with those of Professor Calkins, he did not care to enter at this time into a discussion of that phase of the subject, and would prefer to emphasize the importance of enlisting the cooperation of zoologists and biologists in this work. One of the most encouraging signs of the development of medical research at the present time was that pathologists were recognizing more and more the value of these allied branches of science, and their possible bearing upon the solution of the unsolved problems of medicine. For example, the *Spirochæta pallida* had been seen by some other observers, but its significance as the etiological factor of syphilis had not been suspected until Schaudinn, a zoologist, identified it as a significant structure, and upon the morphology of the organism alone he was apparently able to settle the question of the causation of syphilis.

Dr. C. Am Ende said a similar series of coccobacteria was described by him in the early seventies as the germs of horse influenza. They were round cells, choking with nuclei with nucleoli and spores with sporules, which dispersed with the bursting of the cell and showed all transition forms, from spirule to bacterium. The reaction of this and nearly all other species of pathogenic bacteria to boric acid, similar to that of infusoria and distinct from that of real fungi, demonstrated that they were protozoa. The speaker recalled the fact that the Klebs-Loeffler bacilli varied in form and virulence, and that some contained numerous deep-staining nuclei. Furthermore, Welch described in post-mortem findings necrotic areas with deep-staining dots.

Is Food Containing Sulphites Injurious to Health?—Dr. E. E. Smith, in this paper, said he had pointed out, in a previous article, that the matter of the expediency of using a particular food preservative called for the consideration of three factors, namely: 1. Was the preservative itself injurious to health? 2. Did the preservative lead to injurious conditions in the food to which it was added? 3. Did other considerations render it expedient to permit its use in food? The present paper had to do with the first of these factors in regard to sulphurous acid and the sulphites. The action of the sulphites might be considered

under the following heads. a. In the gastrointestinal tract; b. on the blood; c. on body nutrition; d. on the kidneys. There were three modes of action in the stomach. First, the sulphites tended to neutralize the gastric hydrochloric acid, since by reaction with it they yielded a chloride and sulphur dioxide. This action was, of course, shared by all alkalies, so that as far as the mere act of neutralization was concerned, we were not justified in branding sulphites for that property more than other neutralizing agents, such as, for example, sodium bicarbonate. Indeed, this latter substance entered into the reactions of neutralization even more readily than sulphite. If this action constituted an essentially injurious quality, it must be conceded that so far as neutralizing the gastric juice was concerned, all antiacids were equal offenders. We knew, however, that in the processes of secretion the stomach possessed a relatively wide range of physiological adaptation. The fact of a substance possessing a neutralizing capacity did not alone constitute an essentially injurious quality, since it merely called forth a physiological adaptation. It was only when the neutralizing capacity bore a certain quantitative relation that it became injurious. Dr. Smith said he was not aware of any evidence that peptic digestion was retarded by the presence of sulphites in food, and it might be stated that unless the retardation was reasonably well marked, the action in that particular would probably be within the limits of the physiological adaptability of the organism. In answer to the objection that the sulphites were an irritant to the gastric mucous membrane, the speaker said that such a property was, of course, not peculiar to the sulphites, but was possessed by all diffusible solutes. Chloride of sodium was probably quite as great an offender in that regard. That property, however, was purely dependent on the quantitative relation. In dilute solutions, salines did not possess this property. In other words, we had an action which was not due to an essentially injurious quality of the substance, but which was merely and entirely dependent upon the quantitative relation. Furthermore, there was no reason for believing that the sulphites in food were at all irritating by reason of the sulphur dioxide liberated. It had been maintained that the sulphites produced injury in the blood by causing anemia and by removing oxygen, but the speaker said there was no evidence to that effect. There was no question but that sulphites which gained entrance to the blood were oxidized to sulphates, and to that extent removed oxygen from the blood, but this was so trifling that it could practically be disregarded. Summarizing, it was seen that the injurious action of excessive amounts of sulphites was similar in kind to the harmful effect of other salines, and that such action was due to the quantitative relation and not to any essentially injurious quality of the sulphites; that in the amounts added to food it was not as yet known that harmful effects were produced; that the action of the sulphites in the body afforded opportunity for further experimental study, especially as to the possiiblity of gastric irritation, ferment inhibition, and the production of renal degenerative changes. So far as their action was known, it was their abuse in experimental investigation and not their use in food that had led to harmful results. In conclusion, Dr. Smith said it was not the purpose of his paper to champion the use of sulphites in food, but simply to present the subject for unbiased scientific discussion.

Dr. Willis G. Tucker of Albany, N. Y., said there was much popular misconception concerning food adulteration and the use of preservatives and coloring agents. Many people, including some physicians, obtained their ideas on these subjects largely from the newspapers and sensational articles in the magazines. While there were certain evils in the preparation of our food products which ought to be corrected, nothing was to be gained by deluding the public, and physicians and health officials should not tell people that brewers put nux vomica and cocculus indicus into beer, or that cheap whiskey was a mixture of fusel oil and aqua fortis. Such statements and many others quite as absurd would be found in standard works, so-called, and in recent contributions to high-class reviews and popular magazines. Food preservatives had been used from time immemorial because not many foods could long be kept without them and remain fit for use. When we inveighed against the use of chemical preservatives, we should not forget that salt, acetic acid, and the creosote in wood smoke were as truly chemicals as borax or benzoate of sodium, nor should we entertain the notion that manufacturers of food products vied with each other in their attempts to prepare unwholesome foods, and found strange delight in the use of injurious adulterants and preservatives and poisonous colors. As a matter of fact, precisely the reverse was the case. Ignorant or unscrupulous persons might sometimes use poisons in food, but such intances were rare, and most of us might expect to live out our lives unshortened by poisonous food adulterants, preservatives, or colors. The chief evils against which we should guard were the commercial frauds of substitution, sophistication, and the employment of cheap but harmless makeweights or adulterants; the use of low-grade or inferior material, uncleanliness in the manufacturing processes employed, and, in the case of drugs, the sale of articles of insufficient strength or inferior quality, due often to carelessness in preparation or to decomposition resulting from long keeping or improper preservation. The sulphites, in one form or another, had been used as food preservatives for many years. The sulphuring of wine casks was a very ancient practice, and sulphite of lime had been used for years in preserving cider, and Dr. Tucker said he had never heard of any one suggesting that harm resulted from the practice. The sulphites, bisulphites, and hyposulphites were all more or less employed, more particularly in certain canned goods, like corn, and in meat products, such as sausages and chopped meat. The speaker said he could not learn that there was a tendency to use these agents in increasing quantities, and while he did not think their excessive and indiscriminate use was to be favored, he did not believe that their employment at the present time called for special repressive measures. Such quantities as had recently been reported as found in canned vegetables and in certain wines, ranging from three to 250 milligrams to the kilogram or liter were not very alarming. A great advance would be made if we could secure the proper labeling of food articles, so that compounded, artificially colored, and chemically preserved foods could be distinguished, and purchasers enabled to exercise their discretion when they did their marketing.

Dr. H. W. Wiley of Washington, D. C., gave a brief résumé of the results of the experimental work that had been done in this connection in the Bureau of Chemistry of the U. S. Department of Agriculture. He stated that the administration of sulphites and sulphurous acid in the quantities necessary for the preservation of food produced a noticeable effect upon the consumers, and generally of a hurtful character. A tendency was manifested in every instance to a feeling of illness, loss of appetite, and generally a bad condition. In some cases these symptoms were masked, and not clearly marked; in others they were extremely well defined and easy of detection. The occurrence of this class of symptoms during the administration of the preservative, and their gradual disappearance during the after-period seemed to be conclusive evidence that they could have been due only to the effect of the preservative itself. In many cases uneasy sensations and even pain were developed in the stomach and other parts of the digestive tract, and there were complaints of indigestion, commonly known as heartburn. There were also in some cases attacks of dizziness and palpitation of the heart. In a few cases nausea was developed to the extent of vomiting. The conclusion was inevitable that the administration of sodium

sulphite in the great majority of cases caused headache, sensations of dizziness, occasional nausea, pains in the stomach, and other unfavorable symptoms. In those cases in which sulphurous acid was given in an uncombined state, headache was very commonly produced; there was less tendency to vertigo, but a greater tendency to nausea, and a feeling of exhaustion and weakness. The most dominant symptom was that of headache. It could be stated in a general way that the administration of sulphurous acid in the form of sulphite tended to reduce the weight of the body slowly, and that this tendency was continued for a considerable time after the withdrawal of the preservative. On the other hand, there was a slight increase in the general weight of the body under the administration of the sulphurous acid in the uncombined form. The general effect upon the composition of the feces produced by the administration of the preservative showed that there was a marked tendency to increase the amount of water therein, and thus to act as a laxative. There was also a larger quantity of dry matter excreted in the feces under the administration of the preservative, showing a tendency to produce to that extent an interference with digestion and absorption of the solid bodies during the passage of the food through the intestinal canal. There was thus manifested a marked tendency of this preservative to derange the metabolic process, insofar as the feces were concerned, and this derangement could be regarded in no other light than that of an injurious character. The general effect upon the urine, and that most prominently noted, was in the increase of volume, thus showing a slight tendency to act as a diuretic. This tendency to diuresis was more marked in the cases where sulphurous acid was given in a free state than when it was combined as a sulphite. It was evident, therefore, that sulphurous acid produced a very markedly disturbing effect upon the excretion of the urine, and this could not be regarded in any other light than detrimental. The preservative also had an inhibiting effect upon the phosphoric acid metabolism; it increased the burden upon the excretory organs and the number of albumin reactions in the urine; it diminished the percentage of nitrogen excreted as urea, and slightly increased the percentage of nitrogen excreted in creatinin, thus showing a disturbance of the metabolic activities which could not be considered otherwise than injurious. and finally, sulphurous acid showed a marked tendency to reduce the number of corpuscles, both red and white, in the blood and also to diminish the intensity of the color of the blood.

Dr. J. G. Flanders of the N. Y. State Department of Agriculture said he was glad to hear that such an active interest was being taken by the medical profession in the subject of the healthfulness of food preservatives, and he expressed the hope that this mooted question would soon be settled.

The discussion was continued by Dr. Henry G. Piffard and closed by Dr. E. E. Smith.

Chicago Medical Society.

At a meeting, held November 21, 1906, Dr. Joseph A. Blake of New York City read a paper, by invitation, entitled "The Treatment of Diffuse Suppurative Peritonitis." The paper dealt with the operative and postoperative treatment of diffuse peritonitis, and not with the preventive treatment. The degree of peritonitis in the cases reported was of the type wherein the exudate extended over at least the greater part of the peritoneal cavity, accompanied with definite signs of inflammation of the peritoneum. The extent of the exudate was determined by the return flow irrigator, which method was found reliable. The series included seventy-eight cases of diffuse peritonitis due to appendicitis, contributed by Drs. L. W. Hotchkiss, C. H. Peck, W. Martin, and the author. Thirteen were caused by the perforation of gastric and duodenal ulcers and traumatic perforations of the intestines, all with extravasation of gastric or intestinal contents, contributed by Dr. Peck and the author, and eight cases of typhoid perforation operated on by the author. The series included all the cases of diffuse peritonitis occurring in their services since the treatment to be described was begun. All cases, no matter how severe, were given the benefit of operation. The principles underlying the operative treatment were (1) to remove as rapidly as possible through a small incision the cause of the inflammation; (2) to wash or irrigate the peritoneal cavity; and (3) to use as little drainage as possible and not to attempt to drain the peritoneal cavity. The postoperative treatment consisted in placing the patient in bed in a semireclining position, the administration of large quantities of saline solution by rectum, either by intermittent irrigation with two tubes or by continuous proctolysis; the washing out of the stomach and the absence of food until peristalsis had been established; the administration of morphine immediately after operation, but not after the first twenty-four hours; catharsis was not employed until peristalsis had been established. Washing of the peritoneal cavity was done by the author's double-current irrigator. By it irrigating was done rapidly, requiring from three to five minutes. The advantages of irrigating were the removal of extravasated intestinal contents, and of inflammatory exudates more quickly than can be done by drainage. Irrigating with hypotonic saline solution also prevented the absorption of toxins, not only by the removal of the toxins, but by instituting osmosis by which the water of the irrigating fluids was absorbed into the vessels and the circulation of the patient, while the toxic substances in solution were left behind. Irrigation could be considered as a rapid form of drainage and not attended by its dangers. Deep drains, leading to the peritoneal fossæ, were used only when some material had been left behind after washing, which would tend to prolong the inflammation, such as fibrinous exudates and blood. In all the cases the abdominal wound was drained, the drain passing just into the peritoneal cavity. This was found to prevent suppuration in the wound. In regard to the results in ninety-nine cases there were four in which secondary abscesses formed, two of which were drained, two were not drained. Of the seventy-eight cases caused by appendicitis fifteen died, a mortality of 19.2 per cent., of which seven were not drained and eight were drained. Two of these cases died of complications, the peritonitis having resolved; two were moribund and died shortly after operation; the others died of sepsis and the continuation of the peritonitis. Of the thirteen cases caused by perforation and ruptures of the stomach and upper intestinal tract, four died, a mortality of 30.7 per cent. One of these died of ileus due to adhesions, on the twenty-sixth day after operation; the other three deaths occurred in patients operated on thirty-six hours after perforation. Of the eight cases caused by perforation of typhoid ulcers, four died, a mortality of 50 per cent. In the stomach series, of the cases that recovered, four were drained to the line of suture in the stomach, one to the pelvis, and four were not drained. Of the cases that died, two were drained and two were not drained. In the typhoid series, of those that recovered, two were drained and two were not drained. Of those that died, all were drained. The improvement in the results in the treatment of diffuse peritonitis was due mainly to the rapidity of the operation, with consequently less injury to the peritoneum and shock to the patient; to the use of large quantities of fluids for the elimination of toxins; to giving rest to the intestinal tract, and possibly to the Fowler position. In regard to washing of the peritoneum versus draining, it was still an open question; but definite rules could not be laid down as to the treatment of all cases of peritonitis, as some required irrigation and some not; while, on the other hand, some needed draining and others did better without drainage.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending December 15, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	354	179
Diphtheria	289	42
Measles	163	8
Scarlet Fever	185	11
Smallpox	5	—
Varicella	140	—
Typhoid Fever	51	15
Whooping Cough	71	9
Cerebrospinal Meningitis	3	13
Malarial Fever	.....	.....
Totals	1261	277

Transitory Ophthalmoplegia in a Patient with Arteriosclerosis.—Henri Claude has observed a man sixty-eight years old without previous symptoms who suddenly developed diplopia, accompanied by disturbances of equilibration. There was no paralysis of the extremities. Examination some days later showed a diminution in pupillary reaction, diplopia, a slight divergence of the ocular globes, and a diminution of the movements of the latter. There was also a slight ptosis of the two eyelids. No other nervous trouble was detected, save the abolition of the patellar reflex. There was no sign of nephritis or diabetes. The amelioration of the ocular symptoms was quite rapid, and now there remains only a slight paresis of the external rectus of the right eye and a diminution in convergence. These ocular symptoms appear to have been caused by ischemia of the neuclei of the third, fourth, and sixth pair of nerves. The cause of the trouble was arteriosclerosis.—*Gazette des Hôpitaux Civils et Militaires.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 14, 1906.

ON THE SENSIBILITY OF ABDOMINAL ORGANS AND THE INFLUENCE OF INJECTIONS OF COCAINE UPON IT.

[illegible]

(From the [illegible])

We wish to present a preliminary communication based on animal experimentation on the subject of abdominal pain. Those who have not followed the recent surgical literature on the question of sensibility of abdominal organs are probably not aware of its present status. We might say that it is a perplexing situation. On the one hand there is no fact which is more real than intraabdominal pain. Peritonitis, appendicitis, enteric, biliary, and renal colic, etc., are frequent phenomena in the physician's daily work. On the other hand we are confronted at present with an accumulation of reliable surgical evidence that intraabdominal organs feel neither pain nor other sensations. The discussion of that problem is not of recent date. Since Bichat stated nearly a hundred years ago that he has seen dogs eating their own intestines, many experimental reports have appeared in support of the view that the abdominal organs are devoid of the sensation of pain; but there were just as many reports supporting the opposite view. We are not going to discuss here these contradictory statements of old. The physiological literature of the last few decades contains hardly any investigation on that subject, and in many leading textbooks of physiology there is not a word on visceral pain. The latest large handbook of physiology by Nagel contains a short chapter on that subject, but it is based nearly exclusively on the surgical writings of Lennander. It is the surgeon who now deals with that subject, and for good reasons. For the last quarter of a century surgeons perform, as we all know, very many laparotomies, and since the introduction of infiltration anesthesia by Schleich some of these operations were carried out without general anesthesia. There was then apparently an excellent opportunity of studying the sensibility of abdominal organs—the tranquil and wide-awake patient with a wide-open abdomen could give a better account of sensations than the semi-narcotized dumb beast. Many surgeons have made in recent years more or less systematic observations on the subject in question, but none has carried out a more careful, painstaking, scientific study of our problem than G. K. Lennander, the excellent Swedish surgeon. His observations and conclusions are laid down in a number of articles published in German periodicals. A few years before Lennander, Bier formulated his experiences in a very brief statement to the effect that the intestines can be cut, squeezed, burned, etc., without causing any pain to the patient. Lennander performed a large number of laparotomies under local infiltration anesthesia. Special aids were employed to study the reaction of the patient at every step of the operation. All the numerous observations gave uniformly one result: stomach, intestines, omentum, mesentery, spleen, liver, gall-bladder, kidneys, bladder, uterus, etc., are completely devoid of sensation of pain, and of any other sensations. Only the parietal peritoneum feels pain. According to Lennander the painlessness applies to the normal organs as well as to the inflamed. Many of the earlier observers and a few of the more recent writers who entertained a similar view with regard to the freedom from the sense of pain of the normal organs assumed that inflamed organs feel pain. Most of the present writers, however, seem to accept the view of Lennander also with regard to the inflamed organs.

So far, we had to deal with well observed facts. To the urgent question, What, then, causes the pain in a variety of conditions in the abdominal cavity? Lennander answers as follows: Some pains are caused by pressure, sliding, or pulling of the parietal peritoneum; some other pains are caused by pulling the mesentery, and thus irritating the posterior wall of the abdominal cavity, which is provided with pain fibers derived from the spinal nerves. In other conditions the pain is caused by a lymphangitis and lymphadenitis which reaches the nerves of the posterior wall; and, again, in others some irritating toxic products or chemicals, like hydrochloric acid in gastric ulcer, reach the lymphatics of the posterior wall. In short, all pains come either from the parietal peritoneum or from the spinal nerves of the posterior wall of the abdominal cavity. Other writers offer some slightly different explanation, which, however, we shall not discuss here.

That is the view which is now held by authoritative men practically without any contradiction on the subject of pain and sensibility in abdominal viscera. Internal organs do not feel more pain than dead tissue or our hair and nails. It is obviously a far-reaching view, not only from a theoretical, but also from a practical standpoint. There could be no sense in examining for a painful stomach, a painful liver, a painful appendix, etc., if they are devoid of sensibility; methods in examinations, interpretations, abdominal localization, etc., would have to undergo a radical change.

Casual experiences which we gathered in experimentation on the abdominal viscera made us feel that the last word was not yet spoken on the question of pain in the abdominal organs. We have, therefore, investigated this subject in a series of experiments carried out at the Rockefeller Institute, and we wish to lay before you in a preliminary communication some of our results which we believe are of some theoretical and practical interest.

Our experiments were carried out, or, rather, are still being carried on, on dogs and cats, chiefly on the former. We have employed various methods. The animals were well narcotized by ether, the ab-

domen opened, and immediately closed by temporary ligatures held together by clamps, and when the animal was partly out of anesthesia, one or more of the clamps were taken off, thus permitting one or more of the intestinal coils to come out. These, as a rule, were kept moist and covered with towels saturated in warm saline solution. In other cases the entire animal was kept in a saline bath of 39° C., the viscera being well covered with the warm salt solution. In still other animals the abdomen was opened under local cocaine anesthesia. The presence of sensation of pain was tested by pressing the organs with the fingers or with thumb forceps; by touching them with heated test tubes and by stimulation with the faradic current, and watching the reactions of the animal to these irritations. In all the stimulations great care was taken to avoid pulling the mesentery or touching the parietal peritoneum. We have tested the various parts of the gastrointestinal canal, the spleen, the kidneys, uterus, bladder, etc., but our present statement refers essentially to the gastrointestinal canal which we have studied mostly.

All the experiments lead up to one unmistakable result, which can be stated in a few words: the normal gastrointestinal canal possesses the sensation of pain.

However, that result alone was not yet satisfactory to us. We could not doubt for a moment that the actual observations of Lennander and other surgeons of high standing were perfectly correct. Why, then, this difference in their observations on man and our experiments on animals? Can there be such a fundamental difference between man and beasts? This is not very probable. But besides the difference in the subjects of the observations there was a difference in the conditions under which both observations were made. Lennander operated essentially under Schleich's infiltration anesthesia. Schleich's mixture, as Lennander employed it, consisted of five centigrams of cocaine, one centigram of morphine, and two hundred cubic centimeters of a normal salt solution. It seemed advisable to us as a further step in our investigation to study the possible effect of these ingredients upon the sensation of pain in the abdominal organs. We began with cocaine. The hitherto known effect of this drug is its local anesthetic effect. Lennander and other surgeons employed it for this very quality to deaden the pain during the incision apparently without the remotest idea that the drug could also affect the sensibility of the distant isolated gut. We, nevertheless, decided to test it. After establishing the undoubted sensitiveness of the intestines, etc., two centigrams of cocaine were injected into the tissues of the abdominal wall, near the incision. We were then surprised, indeed, when we discovered that a short time after this injection all sensations disappeared from the intestines; even a very strong electrical stimulus no longer produced any reaction or effect. After thirty or forty minutes the sensations returned. Such observations were then repeatedly made, and invariably with the same result.

Now we could hardly think that the cocaine crept over by capillarity or by some other manner to the intestines, and the observed anesthetic effect was a local one. Neither did it seem probable that the cocaine crept along the spinal nerves to the spinal cord and there came in contact with the pain-carrying nerve fibers from the intestines. The most reasonable explanation was that the anesthetic effect was produced through the circulation. That would mean that cocaine had not only a local, but also a general anesthetic effect. This assumption was easily tested. The cocaine was now injected in parts distant from the abdominal cavity, in the thighs, arms, pectoral muscles, etc. The anesthetic effect upon the intestines was prompt and complete just the same.

In further experiments we have established that one centigram was sufficient to bring out the desired effect, and this even in large dogs weighing 14 kilos.

We have, then, thus far established two facts: that the gastrointestinal canal possesses the sensation of pain, and that the subcutaneous or intramuscular injection of a comparatively small dose of cocaine is capable of abolishing this sensation for some time.

We believe that we are now justified in offering the following interpretation of the surgical observations. While we have not the slightest doubt of the correctness of the facts, namely, that when operating under Schleich's infiltration anesthesia, the abdominal organs are completely anesthetic, we suggest that this anesthesia is due essentially to the general effect of the cocaine employed, and not to a normal absence of sensation in these organs.

Of many details of our investigations which are by no means finished we shall mention here only a few which might have a practical bearing.

In the course of the investigations we exposed some intestinal coils to the drying effect of the air in order to bring on some degree of inflammation, and we then found that inflamed organs are distinctly more sensitive than normal ones; in fact, the sensitiveness is often greater than that of the skin. Now Lennander and other surgical observers stated that in their experience also inflamed organs are completely anesthetic. We have, therefore, tested the effect of cocaine upon the exaggerated sensitiveness of inflamed intestines and found that a somewhat larger dose of cocaine, say three centigrams, will completely abolish all sensations also from inflamed organs.

Another interesting point is the observation that the parietal peritoneum also loses its sensation by a hypodermic injection in any part of the body, but the anesthesia sets in here later and disappears earlier than in the internal organs. It is possible also that the degree of the anesthesia is lower, but we are not yet ready to make any positive assertion on that point.

There is a striking difference in the rapidity of the onset of the anesthesia between an intramuscular and a subcutaneous injection of the cocaine. When injected intramuscularly, the anesthetic effect might be already complete after two or three minutes. Dr. Auer and one of us (M.) reported some time ago on the rapidity of absorption from the muscular tissue of such drugs as curare, adrenalin, and morphine. We can now add cocaine to this group.

An interesting and new fact is the observation which we made on the effect which the injection of a small dose of cocaine exerts upon the psychical condition of the animal; it promptly quiets its excitement. The animals, which were very restless, howling, and crying, became perfectly quiet one or two minutes after an intramuscular injection of cocaine. It may be claimed that the quietness was due to the abolition of the pain. We have tested it on etherized but not operated dogs. On awakening from the ether they howl just as much as operated animals; the howling is not due to pain, but to the ether intoxication. An injection of cocaine quiets them promptly. The psychical effect seems to last longer than the anesthesia of internal organs. The injection has no narcotic effect, the animal is apparently wide

awake, and follows one with his eyes. The lid reflex is not abolished, but the cornea is anesthetic, and the pupil is widely dilated. Whether the general sensibility is also reduced, that question we are not yet ready to answer for the present.

We may add that we made a number of observations dealing with the anesthesia of the intestines reported to have been observed in cases in which cocaine was not employed; but we do not care to embody them in this communication. Our studies are, in fact, as stated above, still in progress.

Résumé.—Our communication may be summed up as follows: The prevailing view based upon exact surgical observations is that the abdominal organs, whether normal or inflamed, possess no sensation of pain. We have found in animal experimentation that the sense of pain is present in normal organs, and that it is considerably augmented in inflamed organs.

We found, further, that a subcutaneous or intramuscular injection of cocaine is capable of completely abolishing this sensation in normal as well as in inflamed organs.

We therefore offer the suggestion that the anesthesia of the internal abdominal organs observed by the surgeons was due to the use of cocaine.

We have finally found that the injection of a small dose of cocaine has a calming influence upon the excitation of the narcotized and operated animals.

It is obvious that both new observations with regard to the effect of cocaine are capable of practical application in medicine.

SCHLÖSSER'S TREATMENT FOR TRIGEMINUS NEURALGIA.*

By OTTO KILIANI, M.D.,

NEW YORK

SURGEON TO THE GERMAN HOSPITAL.

It is unnecessary to describe to the members of this society the clinical picture of trigeminus neuralgia, with which we are all unfortunately familiar. I say unfortunately, because the disease inflicts upon the patients the most horrible suffering, which quite frequently leads to suicide, and because thus far all operations, with the exception of gasserectomy, have proved valueless in so far that, if they ever did any good, it was only for a very short while; and even Krause's operation, with its high mortality corresponding to its seriousness, does not prevent recurrences.

Any proposal of a new method is therefore sure to attract the attention of surgeons, which doubtless would have been the case with Schlösser's treatment also, if his first publication had not happened to be somewhat buried in the report of the Ophthalmologische Gesellschaft of 1903, where surgeons are not likely to look for information.

Schlösser, Professor of Ophthalmology in the Royal University of Munich, published again, in the *Berliner klinische Wochenschrift*, No. 3, 1906, a paper on the treatment of neuralgias by alcohol injections, to which Dr. George W. Jacoby called my special attention. We were both equally strongly impressed with the proposed method of treatment, and during my visit last May to Munich I was shown and taught the method by Professor Schlösser in the most courteous manner.

As long as we know practically nothing about the nature of trigeminus neuralgia—the microscopical examination of excised nerves shows nothing—it seems improbable that one should be able to devise a methodical systematic treatment of the disease. Nevertheless, Schlösser has found in the course of his experiments since 1900 that alcohol, especially in the concentration of 80 per cent., is detrimental to nerve tissue. Thus, an injection of about 1 or 2 c.c. of 80 per cent. alcohol into a sensory nerve will produce, after a short period of pain, a complete anesthesia, which disappears after a number of days, usually about five or six. It is a strange fact that, together with the anesthesia, the tendency to neuralgic attacks disappears, that is to say, the feeling returns, but not the pain. This is, in few words, the *raison d'être* of the procedure.

Permit me now to describe, in short, the technique. To make sure that one really injects into the nerve affected with neuralgia, Schlösser injects into the foramen through which the respective branch emerges into the face, namely, for the first branch the foramen supraorbitale, for the second the infraorbitale, and for the third the dentale inferior. For this purpose Schlösser has devised for his syringe a set of needles of such thick tubing that the edge does not cut at the point of the needle. In that way no arteries, or even veins, are injured by the injection, incredible as it may seem. This point is of special importance, if the injection has to be made into the ganglion Gasseri, in case all three branches are affected. It is impossible to describe the technique exactly, at least in a short paper. It must suffice to say that, in case of an injection into the supraorbital foramen, the needle, being pushed sagitally along the sometimes not very well-defined foramen, must not penetrate the periosteum of the orbit; otherwise the alcohol injected would produce a very pronounced and possibly dangerous retrobulbar edema.

The injection into the second branch is really the easiest, and does not involve any danger.

The injection into the third branch presents the most difficulties; at least, it has given me most trouble. The use of the curved needle devised for the third branch has been given up by Schlösser to a great extent, for reasons which I can appreciate, as it is extremely difficult to feel around the corner, so to speak, in an operation where everything is dependent on the sense of touch.

I may mention here that a successful injection into the inferior dental foramen invariably produces a more or less pronounced tetaniform spasm of the pterygoid and masseter muscles, a mild form of lockjaw, which may last from several days to several weeks. As it is only partial, the patients, who are more or less accustomed to this state of affairs, are quite willing to put up with the condition, if warned beforehand.

To inject into the foramen ovale we use the following procedure: The longest of the three straight needles is pushed through the cheek of the afflicted side about opposite the last molar, the index finger of the left hand is inserted into the mouth as a guide behind the last molar, and the needle then shoved under the periosteum upward along the external pterygoid plate until it is arrested, which takes up about 2¼ inches of the needle. If the handle of the needle, so to speak, is still further lowered, another quarter of an inch can be gained in pushing the needle still further upward toward the base of the skull, when it is definitely arrested. If we feel our way then, backwards, scraping along the bone for about three-eighths of an inch, we feel how the needle enters the foramen ovale, where the injection takes place. It would lead a little too far if I would try to explain how the foramen rotundum is reached without injury to the neighboring parts; but it can be safely done.

*Read before the Surgical Section of the Academy of Medicine at its stated meeting, December 7, 1906.

One understands at once that the technique is a peculiar one, and has to be acquired, as far as possible, on the cadaver, although one is surprised at the difficulties one meets after apparently mastering the technique on the cadaver. I wish to express here my thanks for the great kindness with which Dr. Haynes has put his cadaver material and other specimens at my disposal in my attempts to learn the technique.

But the technical difficulties, great as they are, are not the only ones. The principal thing is the clinical experience which enables us to judge which branch to treat, one or several, or when to attack the ganglion. This is one of the reasons why Schlösser so far has not described his method in detail, because he feels that if it is to become the common property of surgeons and physicians, the minutest rules will have to be given to meet all purposes. This he is doing now by writing a treatise, which will be published the beginning of next year, and of which he has asked me to prepare an English edition.

The injection is done without narcosis; first because it is really not overpainful, and secondly, because one needs the help of the patient in determining whether a small test-injection produces a tingling sensation along the course of the nerve.

The result of a successful injection is at once apparent; for a minute or two there is a sharp, burning pain, similar to a mild attack, to which the patients, who are accustomed to such suffering, do not much object. After an hour or so, there is sometimes quite severe pain for one or two hours, interrupted by typical attacks. Three to four hours after injection, at the very most, the patients are surprisingly comfortable. In one of my cases, the patient, who had attacks every two minutes, who needed a day and night orderly to prevent him from committing suicide, was after the first successful injection free from pain for the first time in years, and slept all night without the administration of any drug, while previously all known sedatives and anodynes, given in dangerously large doses, had proved of no avail. This first injection is usually followed after twenty-four hours by a second one, if the edema is not in the way; a third one the next day, and, if necessary, a fourth one a few days later. Then these patients are cured until the recurrence sets in. This takes place after ten to twelve, to fourteen months. Then the attacks are much lighter, and yield to one or two injections.

This brings me to another point, and that is that since we know that all treatments, even including gasserectomy, are liable not to prevent recurrence, that treatment is the best which permits repetition.

The injection, if executed by a specially trained and skilful surgeon, guided by experience, is without danger, and in its effect is little short of marvelous.

My own personal experience is, in consequence of the short time since I learned the method, naturally limited. The time elapsed since I treated my cases is much too short to judge personally when recurrences are liable to appear. In this respect I have to rely upon the experience of Dr. Schlösser, whose clinical faculties and sane judgment have impressed me very strongly. I have had opportunity to see with him two recurrences, one after eleven, the other after sixteen months; in both cases the patients gladly came back before their condition had become really bad, to submit to repetition of the treatment, to which the attacks promptly yielded.

The treatment is, of course, not limited to trigeminal neuralgia. There is no reason, for instance, why we should not inject the minor occipital nerve if the neuralgia is situated in its region.

If only for the sake of completeness, I wish to mention that Schlösser has extended his method to the treatment of tic convulsif as well as tic douloureux, when he partly paralyzes the facial nerve by injection in the region of the pterygoid process into the surrounding tissue of the nerve. In these cases the dosage, as well as the avoidance of the sheath of the nerve itself, seems to be especially difficult, so as not to paralyze the nerve in question too long; but even here, with the exception of two cases, in which a paralysis resulted for a period up to four months, which afterwards yielded to electrical treatment, he had complete success. Besides that, he has treated mixed nerves, like the sciatic. He claims, and I have every reason not to doubt his word, that even here he has had no serious mishaps with any lasting injury to the motor fibers of the nerve. But, as I have had no personal experience as yet with these nerves, it must suffice to call your attention to the possible scope of the treatment.

I am quite willing to assume the blame of basing my paper upon only such a limited experience as I have had, all the more as I have not had a single failure. In fact, if I had not had more than one single case, cured for the time being, that is, free of attacks, I would not have hesitated to call your attention to this ingenious treatment, which promises to make all operative procedures for these unfortunate sufferers unnecessary.

116 East Fifty-seventh Street.

THE *X*-RAY *VS.* SURGERY IN SARCOMA, WITH REPORT OF CASES.*

By ASPINWALL JUDD, M.D.,

NEW YORK.

ADJ. PROF. SURGERY AND RADIOLOGIST POST-GRADUATE MEDICAL SCHOOL.

WHILE sober judgment and experience have finally definitely condemned the *x*-ray in the treatment of carcinomatous conditions, except in the case of superficially placed epithelioma, to the rôle of a palliative in inoperable cases, its use in sarcoma is still more or less an open question. The writer's experience, extending over a period of time sufficient to observe and treat recurrences, and to feel at least encouraged in other cases that recurrence may happily not be looked for, may prove of some slight value in adding something to the solution of this vexed question. Before proceeding to an analysis of the cases and cause of results, I should like to be placed upon record as believing that all neoplasms of whatever kind and wherever situated, with the possible exception of superficial epithelioma, in which a plastic surgical procedure will not result satisfactorily, should at once be subjected to operation. There are, however, many cases in which, owing to the flat refusal of the patient to submit to operation, to the fact that the tumor is already found inoperable on first examination, and also to the further fact that in a certain class of tumors the cancer, small in itself, will require a grave or disfiguring operation for its removal, the surgeon is compelled to weigh the chances of radiology in effecting a cure. In explanation of the more favorable results obtained by the ray in sarcoma than in carcinoma, I will state what I believe to be the action of the ray in these two classes, which may serve to elucidate an obscure point.

We know that in the *x*-ray tube we have two principal classes of rays useful in therapeutic work. The cathode ray, which has merely the effect of sunlight intensified, and which reacts to the ordinary laws of light, *i.e.* producing hyperemia and sclerosis, not

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, December 7, 1906.

penetrating a dense medium, and so not extending in effect more than 6 mm. below the surface of the skin. The *x*-ray, on the contrary, penetrates all media with intensity depending upon the density, has a selective action upon highly organized tissue, and produces upon epithelial cells first a stimulation, and secondly by overstimulation, a destruction by necrosis, and fatty degeneration of the cell elements. It also causes an obliterating endarteritis by splitting up and destroying the endothelial lining of the terminal blood-vessels, and so deprives the growth of nourishment. It will readily be seen that all structures from the skin down will be more or less subject to the same influence, with a resulting destruction of tissue fatal to our case. As a matter of fact, however, by the time the ray has penetrated to the depths of the tumor, only the first effects of stimulation and, to a slight degree, the endarteritis is effective, and, instead of a destruction of the tumor, stimulation results, with more rapid growth and formation of metastases. As for the disappearance of masses of glands in many cases rayed, pathological examination by Dr. Henry Brooks of glands in cases rayed, and afterward operated upon by myself, have shown that the glands which have disappeared are the seat of nonmalignant inflammation; in no cases where the glands were involved in the carcinomatous process did we find any change.*

The action of the ray in sarcoma is the same as in carcinoma, but owing to the different reaction of tissue the result is far different. The stimulation in these cases causes the changing over of the embryonic type of connective tissue into the adult type, a change from preponderant cells to a tumor mostly composed of fibers; the obliterating endarteritis diminishes the amount of nourishment, and the final result is a fibroma, with possibly latent sarcoma cells included in the mass.

This, I think, will explain the results reported by Pusey, Coley, and others, results with which I entirely agree, as a perusal of cases below will show. Nearly all cases of sarcoma treated by the *x*-ray recur, and in one of my cases this was even true for the third time; but I am somewhat more optimistic than some observers, in that I have found many react to the ray just as kindly the second or the third time as the first. Whether I shall be obliged to go on treating these patients for the rest of their natural lives, or whether they will finally cease to be favorably affected as some of them already have, I have no means of knowing, but at any rate if I can prolong for one or more years in apparent health even a small fraction of these patients, I shall feel that in the *x*-ray we have a remedy which, the knife proving impossible, is better than any other so far suggested.

If we accept as true the theory which I have named above, it follows that in treating our cases we will employ a tube as rich in *x*-rays and poor in cathode rays as possible. This means a very high tube, lighted by a current of considerable amperage, and produced by a coil or static machine of many plates, a small static machine not being effectual in lighting the tube. The distance should be considerable, never nearer than six inches, and usually nine or twelve, to prevent the action of the remaining cathode rays upon the skin. Reaction, as proved by the diminution in the size of the tumor, is usually slow at first. This depends, of course, upon the relative softness of the tumor or preponderance of cell elements. The softer the tumor the quicker the response. In many cases several months have elapsed before there was an appreciable diminution in its size. When our treatment is complete, if we look for an entire disappearance of our growth, we shall be disappointed, for a fibroma will remain. I am in favor of keeping my patients under observation for a considerable time after cessation of treatment, at first once a month, and later once in three months for several years, and resume the ray immediately in case of any change in the remaining mass.

*I have treated this subject more at length in a report of cases of carcinoma of the breast *x*-rayed and afterward operated upon by myself, published in the *Post-Graduate Magazine*, December, 1906.

Case I.—Admitted May, 1903. Pathological examination reveals lymphosarcoma. Examination shows an enlargement of the entire cervical region, beginning posteriorly at the mastoid, extending to the symphysis, and inferiorly to the clavicles. The mass seems to consist of innumerable glands, mostly discrete. The enlargement is so pronounced as to present an almost unbroken contour from the angle of the jaw to the sternum and clavicle. The mediastinum is flat on percussion. The patient has an aneurysmal cough. Enlarged glands are felt in both axillæ. No enlarged inguinal glands. No enlargement of the spleen.

By July the cough and dyspnea had entirely disappeared. The neck had diminished markedly in size, and many of the glands had completely disappeared. There was great improvement in the general health. Clavicles could now be outlined, and the contour of the neck was plainly visible. Patient insisted upon going to the country, although warned that such a procedure would probably prove fatal.

In September the patient returned, with dyspnea and cough as bad as ever. Glandular enlargement also increased about one-half over last examination. Treatment resumed as before. On January 1, 1904, the growth had to all appearances disappeared.

On July 1, 1904, the patient returned for treatment. There was a tumor behind the right ear as large as an egg. The glands above both clavicles were much enlarged, but there was no general cervical enlargement as before. Cough and dyspnea have returned.

May 1, 1905. The patient has ceased attendance at the clinic. At last appearance there were practically no glands to be made out. The cough had disappeared and her general condition was very good.

I have been unable to keep in touch with this case, but my prognosis is bad. The most remarkable feature of this and other cases of lymphosarcoma, pseudoleukemia, and splenomyelogenous leukemia is their rapid reaction to the *x*-ray, but unfortunately their recurrence is just as rapid, and, with the exception of Senn's case, I can find no authenticated case in this country that has remained well long enough to be safely ranked as a cure. The late reports from the German clinics* are quite favorable. I have been able to collect nineteen cases of reported cure, although the length of time that patients have remained without symptoms is not stated. In all these cases of true and pseudoleukemia a rapidly diminishing number of white cells and return to normal of other cell elements is a feature, but after a time in the cases I have seen this has been followed by a destruction of red cells and anemia of grave character.

As we should expect from our accepted theory of the action of the *x*-ray, a toxemia is a regular feature of these cases when the ray is pushed too hard, and invariably follows when the masses have rapidly disappeared. This is a grave danger, and

*Escherich's clinic.

the onset of symptoms of intoxication should be the signal of immediate suspension of the rays until their complete subsidence.

Case II.—This case was presented at a meeting of the society last spring, and is one of melanotic sarcoma. A woman, seventy-four years of age, who came to our surgical clinic two years ago, with a lesion upon the heel about the size of a quarter, ulcerated with a hard indurated border. Pathological examination confirmed the diagnosis of melanotic sarcoma. Amputation was suggested, but refused, and, as a last resort, I subjected her to the *x*-ray. The tumor very rapidly diminished in size, and disappeared at the end of the seventh month. I have been unable to discover any metastatic deposits. Of course, it is as yet too early to claim a lasting cure, nor would I have advised the *x*-ray except as a last resort.

Case III.—Recurrent sarcoma of the glands of the neck. This patient was operated upon three years ago. She presented herself at my clinic in March, 1905, with a growth incorporated in the scar, about the size of an English walnut. The patient was subjected to the action of the *x*-ray, and in April of last year I reported the case as one with disappearance of tumor. In November, 1906, the patient returned, suffering great pain in region of the ear and shoulder. No tumor could be made out, but, believing that pain is due to pressure from a growth, I have again begun treatment.

Case IV.—Admitted to clinic July, 1903. Examination disclosed a tumor on the right side of the head, about the size of a large egg. Pathological diagnosis, spindle-cell sarcoma involving the dura mater. By January, 1904, the tumor was hardly raised above the level of the scalp. Skin and subcutaneous tissue were necrotic, and sloughing over an area about the size of a dime, the result of pushing *x*-ray treatment.

In April, 1904, the patient was transferred to a Baltimore hospital. Improvement was very marked. An irregular depression alone remained. Both tables of the skull were eroded by growth.

November, 1904. A note from the patient informs me that he is quite well and that the wound is healed. While I do not at all count this as a cure, I present the record of the case as showing what can be done for a time at any rate in this class of malignant conditions.

Case V.—This patient was admitted to the clinic January, 1903, with a mass about the size of a child's head in the left side of the abdomen and pelvis, hard, nodular, and firmly attached to the inner surface and crest of the ilium. The patient was exceedingly cachectic and emaciated, about forty pounds under weight. Chronic intestinal obstruction had been caused by the tumor by mechanical action. An exploratory celiotomy revealed a spindle-celled sarcoma of such size and so adherent to the surrounding structures as to be inoperable. Diagnosis made by Dr. Brooks. We began treating this patient with the *x*-ray within a few days after operation, not waiting for the wound to heal completely, although primary union seemed established. The first effect of our ray was to break down this cicatrix, and within two weeks our wound was as widely opened as though no sutures had been employed. I might say, in passing, that this is a common experience if newly healed wounds are treated with the ray. We, however, persisted in our treatment, suspending the same only once for two weeks on account of a small burn, the result of the use of a low tube by an inexperienced assistant at close range.

January, 1903. Patient's strength and nutrition have improved. At the present time he has ninety-five per cent. of hemoglobin, weighs one hundred and ninety pounds, five pounds under normal. Tumor has practically disappeared. Bowels are normal. Seems in perfect health.

December 1. Patient returns to clinic with a recurrence of the tumor, about the size of a grapefruit, with beginning cachexia. Treatment resumed as before. On April 1, 1904, the tumor had again disappeared except for cicatricial tissue. The patient seemed to be in perfect health.

September, 1904. Patient has once more returned, with a recurrence about the size of a lemon.

January 1, 1905. Twelve weeks' treatment has been sufficient to produce a disappearance of the second recurrence.

October, 1906. To date there has been no further recurrence. A small mass of fibrous tissue about the size of a large walnut remains.

This is certainly a case in which the patient was doomed within three months of his first appearance at the clinic in January, 1903, and yet to-day he is alive and well.

Case VI.—Diagnosis: Recurrent sarcoma of the breast. Admitted May, 1903. Patient had a radical operation three months ago. Recurrence began before healing was complete. Examination showed an ulcerated area about three inches in diameter in the site of the wound, involving all the tissues down to the fascia covering the chest wall.

July 1. The ulcer has disappeared. No further evidence of recurrence.

March, 1904. Patient returns with an ulcer about the size of a quarter, surrounded by scar tissue. Treated as before.

June 1. Ulcer has again disappeared. The site of the wound seems perfectly healthy.

October, 1906. Patient remains well up to the present time.

Case VII.—Admitted November, 1903. About one year ago the patient noticed a fusiform swelling on the lower part of the right leg on the outer side, just above the malleolus. A section was removed and found to be osteosarcoma. High amputation was urged, but refused by the patient.

January, 1904. Under treatment the growth has increased in size. The patient's general health is much depreciated. Amputation again advised and refused.

On March 1 the growth had markedly diminished in size. The patient's general health had improved. Weight had increased ten pounds and anemia had diminished.

November. Patient has been under treatment since September 1, more as a precautionary measure than anything else, as no tumor can be distinguished either by palpation or the fluoroscope. Gain in weight about twenty pounds. Patient discharged with warning of a possible recurrence.

In March, 1905, patient returned to the clinic with a rapidly growing tumor at the site of the old cicatrix. Having been about the clinic so long, and become a sort of assistant, he was allowed to treat himself. This has proved a warning to me in allowing inexperienced assistants to focus the tubes, as in six weeks' time he developed a third-degree *x*-ray burn. Treatment had to be suspended, the tumor rapidly developed, increasing very greatly in size. The patient became cachectic and failed rapidly, and in April I performed a high amputation of the thigh. This healed kindly, and the patient's health seemed quite restored. He soon, however, developed a mass of inguinal glands, which were removed by Dr. Edward Peterson, and were found

to be sarcomatous. Upon my return early in September I removed a second recurrence, but the patient rapidly developed metastases in the cord, lungs, liver, etc., and died in October, 1906.

Whether the rapid growth of the recurrence in this case was caused entirely by the faulty treatment or whether it was inevitable I hesitate to say, but I feel that the prognosis in osteosarcoma is more unfavorable than in any other type, with the possible exception of melanotic sarcoma.

We have found in tuberculous conditions that it is rather easy to gain control of the process when involving the glands or synovial tissues, but radiographs show no change in the bones after any amount of treatment. As the tuberculous tissue is much less resistant to treatment than sarcoma, we would argue that in osteosarcoma our prognosis would be still more unfavorable.

Case VIII.—This patient was referred to me by Dr. Peterson after operation for sarcoma, involving the skin of the forehead in the median line just below the line of the hair. A prompt recurrence involving the outer and middle tables of the skull suggested the futility of further operation, except an extremely radical one. The eroded area, when I saw the case, was about the size of a half dollar, and the involved area extended about one-half inch beyond. Treatment with the *x*-ray in the usual manner was begun September, 1905, and after seven months I exhibited the case as one with entire disappearance of symptoms. The skin was smooth and sound, and there were no traces of the tumor to be seen. The patient remained in perfect health until September of this year, when she returned with a recurrence about the size of a dime over site of cicatrix. She has been under treatment as before, and has yielded just as kindly to the ray.

Case IX.—Recurrent sarcoma, involving the orbit, referred September, 1904, by Dr. Roosa after enucleation of the eye. At the time of operation it was found impossible to get beyond the involved area in the orbit, and when I saw the case the orbit was nearly filled with a grayish mass of sloughing tissue. Pain was extreme, so that opiates had to be used during the first six weeks of treatment. After this time pain was almost entirely relieved and the mass rapidly broke down and discharged. All evidences of malignancy disappeared after forty treatments, and the patient was discharged with advice to return on the slightest recurrence of the symptoms.

In March, 1905, the patient returned with a history of pain in the frontal region. As no growth could be made out, and the sinuses by fluoroscopic examination appeared normal, I was inclined to believe that the pain was due to cicatricial contraction. Treatment was administered at intervals for three months without relief, but with no further evidence of tumor. In the summer of 1906 the patient still showed no evidence of new growth, but the pain continued.

Case X.—Recurrent sarcoma, also involving the orbit. Referred by Dr. A. E. Davis in October, 1903, after an operation for enucleation of the eye. In this case the growth had made further progress when first seen, and involved the antrum and left nasal fossa, and had eroded the plate of the superior maxilla. The prognosis was very bad. The patient showed little improvement for months, finally disappearing in April, 1904. In September of the same year he returned, and I was greatly surprised to find not only no extension of the process, but that parts of the tumor had disappeared, and that the granulations looked healthy in places. He continued his treatment until January, 1905, when the neoplasm rapidly increased in size and involved the adjacent areas, and he died with a pronounced cachexia.

Case XI.—Sarcoma of the Pelvis. Recurrent. Referred by Dr. Robert T. Morris. The patient was operated upon in the fall of 1904 for a growth which proved to be sarcomatous, springing from the right ilium about the size of a muskmelon. The tumor promptly recurred, and when I saw the case in September, 1905, it had grown to occupy the entire right side of the abdomen from the ribs to the crest of the ilium, and extended down somewhat into the pelvis. Operation was refused. The patient was failing rapidly in flesh and looked quite cachectic. Treatment with the *x*-ray was at once begun, and continued without intermission three times a week for one year. In September, 1906, a mass, probably cicatricial in character, about the size of an egg, alone remained. The patient's health and flesh were normal, and he was doing a full day's work. I am now having the man report at intervals of a month.

Case XII.—Sarcoma of the Pharynx. This patient appeared in the clinic in April, 1904, with a mass under the angle of the left jaw, extending toward the mastoid, and projecting into the pharynx above the tonsil. Sarcoma was suspected, but as patient refused operation the *x*-ray was applied in the usual manner until October, 1905, when, the mass not diminishing in size and the pain becoming unbearable, the patient was prevailed upon to accept operation. The operation proved very difficult, it being impossible to remove the growth entirely. On pathological examination it proved to be sarcoma. Since the operation the tumor has recurred in spite of further applications of the *x*-ray.

Case XIII.—Mixed tumor, fibrosarcoma and adenoma of the parotid gland. Admitted to treatment November, 1904. Patient had had a small growth in the parotid region for five or six years. Operated upon in October, 1904. It was found impossible, however, to remove the growth without destroying the facial nerve, so intimately incorporated was it in the tumor. The growth was the size of a walnut. By June, 1905, the tumor had diminished more than one half. In September, 1905, two small nodules about the size of a bean remained.

I did not see the patient again until April, 1906, when I found some enlargement of the growth. Treatment was begun once more, and continued until June 1, with the result of once more reducing the mass to its former condition. In September, 1906, an examination of the patient revealed only a very small mass, probably connective tissue in character.

Case XIV.—Sarcoma of the glands of the left side of the neck, operated upon by Dr. Samuel Lloyd; recurrence. At the time I saw this patient, January, 1905, he also had a deposit in the left pleura of considerable extent. He was suffering great pain in his side and back, was quite cachectic, and seemed a hopeless case. I consented to use the ray, thinking we might relieve his suffering. In this case I administered the treatment for fifteen minutes over the chest, also for same length of time over the cervical glands, and used a specially constructed tube for ten minutes additional, to try and get at the sphenoid. The case being hopeless, I disregarded the toxic effect of prolonged dosage, thinking only of the analgesic effect. Much to my surprise, the pain in the chest and difficulty in respiration diminished rapidly, the glands in the neck also decreased greatly in size, until in September, 1905, had it not been for the pain in the head ascribed to the growth in the sphenoid, the patient

would have been in fair condition, having regained much of his lost flesh. Treatment was continued during the winter three times a week, but the pain in the head became so violent that it was necessary to use morphine in considerable quantities. I do not think we ever affected the growth in the head by the ray.

In March, 1906, the patient died. At the time of his death the glands in the neck had nearly disappeared, and the pain and growth in the pleura were practically absent. On percussion I was unable to make out more than a thickening of the pleura.

In nearly all the cases presented I administered thyroid extract in dosage as large as it could be tolerated as part of the routine treatment, and found that the cases were more favorably affected and resolution of the masses was more rapid under its use.

Of the cases presented, five patients are dead or unimproved, six have no further symptoms of malignancy, and three are somewhat improved.

This does not include all the cases of sarcoma treated during the past four years. Many were treated for too short a time to form any opinion as to the result, some disappeared after several months with apparently favorable results, but we have been unable to keep in touch with them. Quite a number were so evidently hopeless when seen that it would be unfair to include them in this list, which contains only those which we were able to keep under observation for a considerable period of time. I think the cases presented fairly represent the work done and results obtained.

In conclusion, I wish to reiterate that this paper is in no sense a plea for the *x*-ray in sarcoma, but rather an effort to place the agent in its proper place. In these days when overenthusiasm and extravagant claims have done so much to discredit the entire range of radiotherapy, I wish if possible to point out its narrow but nevertheless positive field of usefulness in this condition.

137 West 69th Street.

NOTES ON FEVERS IN THE TROPICS.

By E. S. GOODHUE, M.D.,
HOLUALOA, KONA, HAWAII.

RESIDENT PHYSICIAN NORTH AND SOUTH KONA; IN CHARGE THE DOCTORAGE; MEMBRE DE LA SOCIÉTÉ DE MÉDECINE ET D'HYGIÈNE TROPICALES, PARIS.

If the tropics have not produced the investigator and discoverer himself, warm countries have at least furnished him with an incentive as well as the material and conditions necessary for the successful prosecution of his work. It was a French surgeon at Algiers who discovered the parasite of malaria, and Ross of India who demonstrated its complete life cycle. Celli, of a subtropical country, added valuable contributions, aided by Nott, Koch, King, Flügge, Pfeiffer and Manson. Koch sought the jungles of Africa, and young Manson lost his life in malarial regions, whither he had gone in search of scientific data.

Hawaiian Fever.—At the last annual meeting of the Hawaiian Territorial Medical Society, Drs. Mori and Kuramoto of Honolulu made a short but interesting report on work they had done in the investigation of some of our obscurer fevers.* They said:

"About twenty years have elapsed since Japanese people began to immigrate to these islands, and during this period about a thousand of them fell as victims of a species of typhoid fever, which occurred sporadically and epidemically. Dr. T. Iwai designated the fever as 'Hawaiian fever,' when it occurred with a severe epidemic type at Hilo, eighteen years ago, finding a slight difference from typhoid fever in its clinical aspect.

"Generally speaking, the clinical symptoms of Hawaiian fever are those of a mild infection of typhoid fever, but in analyzing the symptoms the former differs from the latter in the following respects: (1) In typhoid fever there are premonitory symptoms of a few days' duration; in Hawaiian fever there were none. (2) Typhoid fever is characterized by a gradually increasing daily rise in temperature. In Hawaiian fever the rise is more sudden and reaches its acme in from three to four days. At the fastigium the remissions are marked in Hawaiian fever, while they are very slight in typhoid fever. In typhoid the fall of temperature is gradual, the descent being steplike. In Hawaiian fever the fall, in the largest proportion, is sudden, and only in a few was the descent by lysis. (3) The tongue in typhoid is dry, brown, and furred, while sordes is not uncommon. In Hawaiian fever the rule is that the tongue is moist and covered with a white coating. (4) The spleen is not palpable usually in Hawaiian fever. (5) The tympanites is not extensive nor distressing in Hawaiian fever, as in typhoid. (6) Delirium is of rare occurrence in Hawaiian fever. (7) Emaciation is not extreme in Hawaiian fever.

"In October, 1903, Kuramoto isolated a species of bacillus resembling the bacillus typhosus from the feces of a fever patient and named it the 'Yasuda' bacillus after the name of the patient. Thinking the Yasuda bacillus to be the pathogenic germ of Hawaiian fever, Kuramoto tested the agglutination reaction of the sera of many fever patients on Yasuda bacilli with positive results. But he was rather amazed when he found that the sera of some patients had an agglutination on both Yasuda and typhoid bacilli. During September, 1904, Dr. Shiga, the discoverer of dysentery bacillus, passed this port and gave a culture of B group of the paratyphoid bacillus.

"Now, enough materials have been in our possession for comparison, and Kuramoto thinks that the morphological character of Yasuda bacillus resembles the bacillus typhosus, but differs in the following biological points: (1) Yasuda bacilli produce an alkalinity in the litmus milk. (2) Yasuda bacilli agglutinize by the sera of Hawaiian fever patients in the dilution of over 1 to 100, but no agglutination by the sera of typhoid patients. (3) Dr. Uchida thinks that the Yasuda bacillus rather resembles Conradi's B group of paratyphoid morphologically, but only differs in the point of not producing gas in glucose agar.

"During the past two years 142 fever patients were admitted to the Japanese hospital in this city, and they could be classified into the following three groups: (1) Fifty-three Hawaiian fever, which only had the agglutination reaction on Yasuda bacilli. (2) Thirty-seven typhoid fever which had genuine Widal reaction. (3) Fifty-two double infection, probably, which had agglutination reaction both on Yasuda and typhoid bacilli.

"But whether the reaction of the third group due to the double infection, or the group reaction, is the subject to be investigated, the following question and phenomena are to be investigated: (1) Is Yasuda bacillus quite an independent bacillus, intermediate between the typhoid and colon bacillus? (2) The relation of the agglutination of typhoid, paratyphoid, and Yasuda bacilli to the sera immunized by each bacilli. (3) Pfeiffer's phenomena of the bacilli of the three species."

*"Preliminary report on 'Hawaiian Fever' Research." By Drs. I. Mori and K. Kuramoto. Trans. Hawaiian Terr. Med. Society, 1905.

To conservative students there may seem here an overeagerness to establish new series and nomenclature, but no one will deny the value of the enthusiasm shown. "Hawaiian fever," even if the class be definitely differentiated, would hardly be a good name for a disease that may not belong to Hawaii alone. The name had better be expressive of some phase of the disease. While the morphological findings are extremely interesting, they are far from conclusive, and the clinical differences are not so variant that they cannot be included under some one of the forms of typhoid fever.

Malaria.—Early in 1899 the Pathological Society of London examined a case of Blackwater fever and began a discussion that extended to most of the medical societies. The disease was first described by a French physician in Madagascar. Men on the ground commenced making observations, and positive opinions came from little towns as obscure as Batanga in Africa. In May, 1902, Dr. Curry, appointed to investigate the diseases of the Philippines, reported two cases of hemiglobinuric fever, and in August of the same year a new variety of anopheles was described by the discoverer, Dr. Ludlow. It was called the *Anopheles philipinensis*. Allied hemorrhagic fevers prevalent among whites in Texas are shown to be different from ordinary malarial fevers. Dr. Shropshire has demonstrated this by a careful record of cases. The study of the many forms of malaria, or at least of its many manifestations, particularly as to symptomatology, is continued by Dr. Penn of Tennessee, while Dr. Hoppel of the same State shows conclusively that his one hundred cases of fever were not typhoid, though his conclusion as to their nonmalarial origin is not so well founded. In 1904 Powell of Bombay reported on the examination of 3,413 cases of fever, finding parasites in 2,542. In the remaining 761 cases "definite diagnosis by clinical methods was made in 531, leaving 214 cases of fever whose cause is uncertain."

"Here, then, are at least this number of cases of indeterminate fever," says the *Journal of Tropical Medicine* (May 1, 1906), "which only a few years ago would undoubtedly have been ascribed to malaria. But what of the 531 cases diagnosed by 'clinical methods,' and what real ground is there for assuming them to be malaria at all?" James Cantlie in a recent paper says very truly: "Another point that presents itself is the comparative rarity of serious cases of malaria in tropical practice. Far more than nine-tenths of those met with are what are commonly spoken of as 'touches of fever,' lasting from a day to a week or even more. Most of these are undoubtedly malarial—they are, moreover, mostly fairly amenable to quinine. Every now and again, however, a severe prolonged case of fever presents itself, in which quinine has no effect whatever."

Dr. E. V. Watkins, from observation in two soldiers serving in the Cuban war, is convinced of the "simultaneous occurrence of typhoid fever and malaria in the same patient." This was demonstrated by Widal's reaction and the finding in one case of the estivoautumnal and in the other tertian parasites in the blood. (MEDICAL RECORD, June 25, 1904.)

Dr. W. C. Gorgas, Chief Sanitary Officer of the Canal Zone, Panama, made some interesting statements in regard to malaria before the last annual meeting of the American Society of Tropical Medicine. He said that while the percentage of deaths is not nearly so great in malaria as it is from some other diseases common in the tropics, yet the amount of physical incapacity caused among laborers by malaria is far greater than that from all the other diseases combined.

Malta Fever.—Of Malta fever the *Journal of Medical Research* (July, 1901) says: "There is reason to believe that the disease will soon exist in the United States, for its existence in the Philippines has been conclusively demonstrated and cases have been reported from Porto Rico, and from both these places patients suffering from the disease have returned to the continent. Typhoid fever, malaria, and rheumatism were readily excluded." The study of the disease has been rendered easier by the work of Drs. Strong and Musgrave, who, without preconception of any sort, followed scientifically the clinical aspects of some Manila cases. Later, Dr. Stanley, Health Officer of Shanghai, reports the examination of a large number of fever cases. "During 1904 nine specimens of blood from suspected cases of Malta fever were examined, and seven of these gave the Widal reaction with the Malta fever organism. Of 27 specimens from suspected cases of Malta fever, 10 gave the Malta fever reaction. Clinically, the cases were reported as corresponding to Malta fever."

Lieutenant Kennedy of the Royal Army discovered in a patient with Mediterranean fever organisms "identical in character with the *Micrococcus melintensis.*" Of Mediterranean fever several monographs by officers living in India give valuable information which is very recent.*

So far as Malta fever is concerned, there may be no great danger of its spread, but for clinical as well as scientific purposes it deserves careful study, because its early stages are so easily confounded with malaria, and, later, it so closely resembles chronic rheumatism. It is just possible that Malta fever and not rheumatism is what ails so many "rheumatics" down South. Drs. Musser and Sailer have shown its prevalence in Porto Rico: "The serum reaction of the disease is so reliable and the test is so easy of performance that all cases with doubtful fevers in the Southern States should be subjected to it."

Hawaii offers a rich field for the study of fevers.† Typhoid is a good name to placard indeterminate epidemics with, but, to many of us, it is far from satisfactory. In such limited epidemics as those on Molokai and Hawaii, how much could be accomplished by the careful work of a man who had time to investigate them? I have no doubt that, as in the fevers called "calentura," so well described by Dr. Foxworthy of the Philippines, we would find in them neither *Bacillus typhosus* nor *Plasmodium malariæ*, and we might help to clear up a variant type of fever not uncommon among Hawaiians, marked by contagion, persistence, recurrence, and often a fatal ending.

A fever, called by Dr. Doherty "Manila fever," occurring during the hot months of April and May, resembles a fever which has been prevalent in Kona (and probably Waipio), Hawaii, during warm, dry seasons.

Dr. Bacones says that Manila fever is not found outside of Manila. Out here in the country an experience with about 25 cases, presenting many typhoid symptoms, confined to neighbors, with a mortality of about 9 per cent., might well incline the attendant to term the manifestation typhoid. At the

*"Mediterranean Fever: Isolation of the Micrococcus Melitensis." By Capt. Geo. Lamb and Ass't Surg. M. Kesava Pai.

†It is only fair to the writer to say that these remarks about fevers were made before he knew of the investigations being carried on by Drs. Mori and Kuramoto.

same time he hesitates over the failure of his test reaction, and with the clear typhoid source theory in mind, wonders how typhoid fever can originate without antecedents.

Is the fever which some of us have observed in the presence of high temperatures on leeward Hawaii siriasis? Or is it cerebrospinal fever, or tuberculous meningitis? Pain, vertigo, headache, thirst, mental confusion, and paralysis occur in course. Siriasis occurs in coast regions of the South, South America, Australia, and in the hot, dry countries generally.*

Yellow Fever.—It hardly needed the recent report of the French Commission to confirm the observations of Reed, Lazear, Carroll and Agramonte that *Stegomyia fasciata* is responsible for the spread of yellow fever. But the report contains most valuable data, as: "The mosquito can only acquire power of infection during the first three days of the patient's illness. Twelve days must elapse after the mosquito has imbibed the virus before its bite can infect human beings. The infected mosquito retains its power of infecting man as long as it lives—namely, twenty to thirty days. *S. fasciata* requires human blood for the development of her eggs. The first generation of the offspring of an infected mosquito seems capable of transmitting yellow fever fourteen days after reaching full development."

Though Dr. Findlay told us twenty years ago that the mosquito was an agent in the transmission of yellow fever, we did not learn much about it or its methods until Drs. Manson and Ross, with unabated tropical enthusiasm, made the matter clear as day. But Dr. Ross, who has received the Nobel prize for his work, gives due credit to America: "The discovery of at least one mode of infection of yellow fever—a discovery of the highest importance to mankind—emanates from America."

Sanarelli's faithful work provoked further investigation, and though his theories were found to be erroneous by Dr. Reed and his associates, his methods of work were approved. Perhaps in all great discoveries those who point the way, who suggest possibilities to others, deserve the most credit. It takes a man of rare genius to look across the misty spaces—the man who penetrates the fog after he has been told what he will probably find is no more than many other men. Of the labors of members of the United States Public Health and Marine Hospital Service in Mexico, Guiteras in Cuba, and Salembi and Simonds in South America, Dr. Blumer says: "New discoveries in medicine have led to more rapid and more brilliant results."

Dengue or Breakbone Fever.—While the symptoms of this "specific and highly infectious" fever are well known to us in Hawaii, we have added nothing to the meager information supplied by medical science thus far. Dr. Manson says that most all tropical countries have been visited by dengue; that it occurs in widespread epidemics, extends with rapidity, assuming pandemic characters about once in every twenty years. It is most frequent in the West Indies. If it goes north it does so only in summer, like the birds, and while not a fatal disease it is very painful and often leaves a patient to the prey of more serious diseases.

The etiological factors of the disease still remain unknown. Drs. Sutton and Carter have studied it in Panama, and Dr. Graham claims that the mosquito transmits it, yet despite its occasional prevalence in the Southern States and the severe epidemics of 1892 and 1903 here and in the Philippines, we must classify it as little understood.

*Swollen Head Fever.**—This title need not cause a smile, though the name is one which we are wont to look upon with levity. It is reported by Dr. W. J. Goodhue, resident physician at the Leper Settlement on Molokai: "This is the second epidemic of the kind which has occurred at the Settlement, the first happening about four years ago during the incumbency of Dr. Oliver, who unfortunately left no notes. In conversation with one of the Sisters—who has been with the lepers here for over twenty years—I learned that she had never seen this phase of the disease. Dr. Oliver expressed himself to her as being puzzled at this 'new disease.'

"Swollen head fever is an acute epidemic, painful inflammatory fever, in which the head and face become greatly swollen and in which the lymphatic and glandular system become characteristically involved, especially the cervical, and sometimes the axillary and inguinal as well. This ailment is a distinctively leprous fever—differing materially from 'leper fever' in its symptoms, temperature curve, course, prognosis, and treatment, but due to the same specific virus, somewhat modified and more active. While the bacilli are not found normally in the blood of lepers, I was enabled to obtain a specimen from three of my most characteristic cases, in the blood of two of whom I was able to demonstrate the bacilli. I am confident that during the acute exacerbation of the temperature when the patient's chill shows the activity of the elements of infection, the bacilli are liberated in great numbers in the blood, to be disseminated throughout the system. The appearance, contagiousness, and temperature resemble erysipelas so closely that I was led to search for the germ of this disease as well. While the affection proved to be highly contagious, not one of the score of nonlepers (kokuas) constantly exposed to it became infected, showing conclusively that leprous tissues are necessary for its propagation and activity. Further investigations will be made in this line when opportunity offers.

"The onset is usually sudden and begins with a severe chill. This chill is succeeded in about half an hour by rapid rise in temperature, the thermometer in the mouth registering between 104° and 105° F. The submaxillary and auricular glands about this time become enlarged and painful to the touch, as well as the skin all over the head and face. Swelling begins on the head or face, or both, on the same side as the enlarged glands, and gradually extending to the other side, when the whole face may become so enlarged and disfigured as to be unrecognizable, especially in the numerous cases in which the patient's eyelids become so swollen that in many cases they cannot be opened, and the unfortunate endures temporary blindness in addition to his other miseries. About the third day the swelling extends to the glands of the other side of the face, and these, with adjacent tissues, reach their maximum size and severity in about three days more, when they remain stationary until between the eighth and ninth day. The swelling gradually subsides, the pain disappears, and the temperature, having followed very closely the glandular infiltration and swelling, rising rapidly to 104°-105° or thereabouts with the first invasion and then jumping to 104 4-5° or 105 4-5° F. with the second invasion, drops rapidly to 99° F., or normal, upon the first subsidence of the inflammation.

*Report of Board of Health, 1904.

*"There have been small epidemics of typhoid fever in the Pelekunu and Halawa Valleys, Molokai, Waipio Valley and Waimea Hawaii, and also in the Kona Districts. Those affected were nearly all Hawaiians." Report L. E. Pinkham, Pres. Board of Health, 1905.

"In about 15 per cent. of the cases, however, the axillary and inguinal glands become involved during or immediately after the subsidence of the primary swelling, diffuse hypodermic swelling, and infiltration of adjacent skin and superficial tissues, progressing rapidly and extending along the lymphatic channels to the extremities. Occasionally it is circumscribed and may encircle an arm or leg. The skin of the affected area is very much congested and sometimes deeply pigmented. Here numerous millet seed to lima bean sized blisters form, which break and leave a raw, angry looking surface, slow to heal. The temperature takes a fresh rise up to 102° F., remaining almost stationary until the skin becomes nearly normal again. When this complication occurs, the patient does not become convalescent for from ten days to two weeks later. In the uncomplicated form the patient is convalescent from the acute symptoms in two weeks.

"Suppuration in the cervical glands may have occurred (and did occur in 9 per cent. of my cases), in which convalescence is somewhat delayed; but in every instance the patient is slow to regain his former tone and vigor, and reconstructive tonics are required. After the fever has left, the patient's hair all falls out, and desquamation of the skin occurs in the face, neck, and ears.

"In the aged and debilitated the prognosis is grave. In strong children and adults the mortality is very low."

THE BURSTING OF THE STANDARDIZATION BUBBLE.

By WILLIAM J. ROBINSON, Ph.G., M.D.,
NEW YORK.

When manufacturers of galenical preparations began to announce that they were offering assayed or standardized fluid extracts and tinctures, they showed that they no longer could disregard the constantly growing demand on the part of the medical profession for a certain amount at least of accuracy in therapeutics. They no longer could disregard the fact which was becoming gradually more and more patent to the discriminating part of the profession, that in many cases the use of the uncertain galenicals was nothing short of criminal. Standardization was a step in the right direction. It showed a desire to give the profession preparations of more or less uniformity. But standardization is merely a step, a single step, in the evolution of an exact and definite materia medica, and to stop there would be to rest on a broken reed.

I believe the arguments I am about to present are absolutely unanswerable, and I should be pleased to hear what can be said in their refutation.

First, I shall show the absurdity of standardization. Let us take aconite, for instance. The Pharmacopœia gives an extremely troublesome method for standardizing the fluid extract of aconite so that each 100 c.c. of the fluid extract may contain 0.4 grams of aconitine. Now, what is all the trouble for? Either aconitine represents the virtues of aconite, or it does not. If it represents the virtues of aconite, then why not use aconitine *per se?* For even the most enthusiastic believer in galenicals will admit, that if we have an active principle which fully represents the parent drug, the administration of such active principle is in every way preferable. We need only mention the smallness of the dose, convenience of administration, absolute exactness of the dose administered, unchangeability, invariability through evaporation, etc. If, on the other hand, the aconitine does not represent the full activity of aconite, if the aconite possesses something else of value besides the aconitine, something mysterious, which cannot be isolated and standardized, then to what purpose is the standardizing for aconitine?

In the case of other drugs the absurdity is still greater. Pilocarpus, for instance, contains two principal alkaloids, pilocarpine and jaborine. The action of jaborine is directly antagonistic to that of pilocarpine. Now, of what good is it to know how much pilocarpine a certain fluid extract contains if we do not know how much jaborine it contains? Suppose the fluid extract of pilocarpine does contain 0.4 per cent. of pilocarpine, as the Pharmacopœia directs. Of what good is it if we do not know whether the amount of jaborine it contains may not entirely overshadow the action of the pilocarpine? It is clearly evident that a fluid extract with but 0.3 or 0.2 per cent. of pilocarpine, but a very small amount of jaborine, may still prove more efficient than a fluid extract of 0.4 per cent. of pilocarpine, but a very large percentage of jaborine. Will any honest standardizer kindly answer the above arguments?

I have shown briefly but conclusively the absurdity of standardization. I shall now show what a broken reed standardization is, demonstrating its utter unreliability, and in many instances its utter worthlessness.

Let us assume for the present, for the sake of argument, that standardization really standardizes, that when a fluid extract just finished is stated to contain a certain percentage of alkaloids, it really contains that amount. What guarantee is there that the same percentage will be contained in it a month or six months, or a year later? Are not the temperature, exposure to air, evaporation of menstruum very liable to cause the precipitation or decomposition of the active principle contents, or change their relative proportion? That this is not merely a possibility or probability, but an actual fact, will be seen from the statement made by one of America's foremost wholesale druggists.

The New York Board of Health has recently been investigating the condition of the drugs purchased directly from the wholesale trade. The investigation disclosed the shocking fact that 72 per cent. of all the drugs purchased from the wholesale trade were below standard, and but 28 per cent. came up to the Pharmacopœial requirements. Many fluid extracts were found practically or entirely devoid of alkaloidal contents. Mr. William Jay Schieffelin referring to the Board of Health findings, made the following significant statement: "Some of the extracts which the Board of Health reported below standard were found to be of proper strength when made, but the active principle had deteriorated. This led to the suggestion, which has been approved and adopted by the manufacturers, that a dated label be placed upon all such extracts, and that they be sold in small containers, so that the druggist can constantly have a fresh supply."

Here is a statement that the active principle in galenical preparations may and often does deteriorate. If this is the case, of what value is standardization? Suppose a fluid extract of cholchicum did contain when made 0.5 per cent. of colchicine, what guarantee have we as to how much it contains now —when six months or a year old? It is well known that many fluid extracts and tinctures are kept on the druggist's shelves for years, and to offer such galenicals to the physician as reliable weapons in the fight against disease, because at some time in the past they were standardized, is farcical in the extreme.

But let us look a little closer into the subject of standardization. The average physician, as well as the average pharmacist, is under the impression that the processes of assay are something definite, perfect, immutable. That when a person states that a certain galenical has been standardized to contain a certain amount of active principle, that it is always so, must be so. The well informed have always known that it is *not* always so; that standardization depended a good deal upon who the operator was and upon the method adopted. In other words, two equally competent operators using the same method of assay might obtain a different result, and the same operator using different methods of assay would obtain different figures. We also knew that several assay methods of the Pharmacopœia were either unreliable or entirely *unworkable.* But something has recently happened which will, or should open the eyes of a good many who worship at the shrine of standardization. At the last annual meeting of the American Pharmaceutical Association held at Indianapolis, Prof. H. M. Gordin of the Northwestern University School of Pharmacy, universally acknowledged as one of our foremost authorities in alkaloidal chemistry and standardization, threw a bomb into the Pharmacopœial committee on assays by declaring publicly that several of the Pharmacopœial assay processes were "completely unworkable." In his paper entitled "Some Alkaloidal Assays," he makes the following statement (*American Journal of Pharmacy,* p. 458, October): "While most of the methods adopted in the U. S. P. of 1900 for the alkaloidal assay of drugs and galenicals are very good, there are a few among them that either do not work at all or are so complicated that they will hardly ever give concordant results in the hands of different chemists. To the first class belong the assays of aconite root, its fluid extract, and the fluid extract of ipecac. In these assays we are directed to filter the first acid liquids obtained in the method, but as these liquids are very thick and slimy they soon clog up the filter and the assays cannot be finished. To the second class belong . . . the assay of extracts of physostigma and conium, and a few others."

In another paper entitled "The Alkaloidal Assays of the U. S. P. of 1900" (see same issue, page 454), Prof. Gordin makes the following statement: "Some of the assay methods of the Pharmacopœia are completely unworkable. Such, for example, are the assays of aconite root, its fluid extract, and fluid extract of ipecac root, in all of which we are directed to filter the first acid liquids obtained in these assays, but as these liquids are very thick and contain sticky resinous substances, the filters are very soon completely clogged, and the assays cannot be finished. This is in accord with my own experience and the experience of several teachers and students in our school."

Now, if our foremost authority on standardization finds many of the Pharmacopœial processes either entirely unworkable or capable of giving discordant results in the hands of different workers, what may we expect from the ordinary chemists in the galenical departments of our various wholesale drug houses?

And in parentheses I would ask this rather indelicate question: How did the various wholesale drug houses standardize, for instance, their fluid extract of aconite according to the U. S. P., as they declare on their labels they did, if, according to Prof. Gordin and other most competent chemists, the assay process was entirely unworkable and could not be finished at all?

Prof. Gordin was not alone in his strictures on the U. S. P. methods of assay. Prof. J. M. Francis, Prof. A. B. Lyons, and other speakers agreed with Prof. Gordin, and pointed out serious defects in many of the methods. The subject seemed so important that Prof. Rusby of the New York College of Pharmacy introduced a resolution demanding that the processes be revised, and that a supplement to the Pharmacopœia be issued (see *Bulletin of Pharmacy,* October). This proposition, which is an open accusation of incompetent work, was naturally opposed by the chairman, who suggested as an alternative that the criticisms be referred to the subcommittee on assay processes for such action as the latter might deem necessary. And, we might add, the assay processes of essential oils met with similar criticisms, and the chairman of the subcommittee on assays of essential oils confessed that the processes were admitted without verification as to their workability or correctness! To summarize:

Standardization is useless: (1) When the active principle fully represents the drug it requires no argument that standardization is useless, and worse than useless, because the active principle offers indisputable advantages in (*a*) smallness of dose, (*b*) convenience of administration, (*c*) exactness of dose, (*d*) freedom from objectionable and irritating inert material, (*e*) nonchangeability (*f*) nonvariability, (*g*) and more rapid absorption. (2) When the active principle does not represent the drug in every respect, standardization of one active principle is worse than useless, because it gives no information as to the absolute and relative amount of the other active principles, and does not provide for the removal of antagonistic principles.

Standardization is unreliable, for even if the galenical preparation, when made, contains the exact percentage of active principle, the latter soon begins to deteriorate; changes in temperature, exposure, evaporation, cause a change in the menstruum, which in its turn produces precipitation, etc. That such deterioration is actual, and not hypothetical, has been publicly acknowledged by one of the most prominent manufacturers of galenical preparations.

Standardization is unscientific and imperfect. Processes of assay as found in the Pharmacopœia, which one would expect to be reliable and to give definite results, have been declared by the highest authorities to be unpractical, utterly unworkable—and to give discordant results in the hands of different chemists.

All this being the case—and that it is the case is publicly acknowledged by the manufacturers of galenicals and adherents of standardization themselves—is not the question legitimate? What is it all for? Why not go to the root of the matter, give up most of the galenicals, and use, wherever feasible, the active principles instead?

A PLEA FOR THE SIMPLE ROUND-LIGAMENT VENTROSUSPENSION.

By B. S. TALMEY, M.D.,

NEW YORK.

GYNECOLOGIST TO THE METROPOLITAN HOSPITAL AND DISPENSARY, FORMER PATHOLOGIST TO THE MOTHERS' AND BABIES' HOSPITAL, ETC.

In retrodisplacements of the uterus there is more or less a torsion of the broad ligaments, which causes an obstruction of the blood supply, and thus a passive hyperemia of the entire genital apparatus. The result is a hypertrophy of the myo- and endometrium and the great variety of vexatious symptoms.

When we consider the multitude of these symptoms, as the discomfort, the sense of weight, inabil-

ity to walk without pain, backache, pain in the lower abdomen radiating down the thighs and hips, vesical and rectal tenesmus, pain at menstruation, dyspepsia, palpitation of the heart, neuralgia, headaches, and the irritable type of nervousness which is characteristic of retrodisplacements, we must not

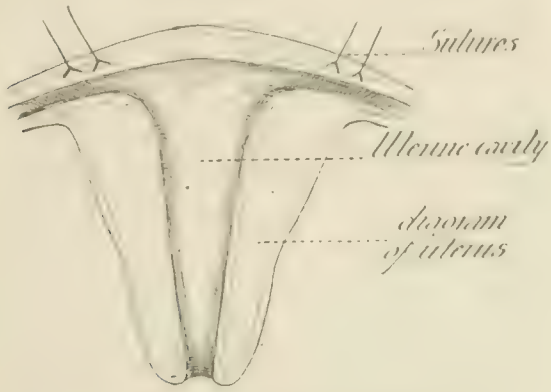

FIG. 1.—Kelly's suture above the uterotubal junction.

wonder that the physician was always on the alert to discover means for the correction of these displacements. Before our present operative era the correction was possible only by means of pessaries, and medical ingenuity invented a great variety of these instruments.

In 1877 Koeberle first conceived the principle of suturing the stumps of the tubes and ovarian ligaments to the tissues of the abdominal incision after castration. Three years later Tait tried to cure a retroversion by suturing the fundus to the abdominal wall after he had removed the diseased ovaries. Olshausen recommended in 1886 the attachment of the pedicles of the tubes and ovarian ligaments to the sides of the abdominal wound with inabsorbable material after castration. In his second case Olshausen secured the uterus to the abdominal wall by passing the sutures through both cornua uteri at the attachment of the round ligaments and the tissues of the abdominal incision. He claims that this method offers a stronger hold of the uterus than suturing only one pedicle, and, on the other hand, that it secures a better mobility of the uterus.

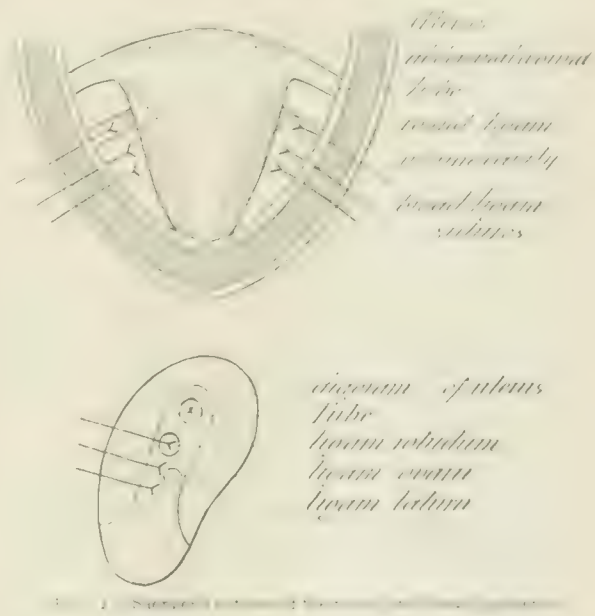
Kelly, in 1887, also recommended that both tuboovarian pedicles be utilized to attach the body of the uterus to the anterior abdominal wall. If the operation be performed simply for retroflexion, without removal of the appendages, Kelly advises the sutures to be passed including only the round ligaments or, better, above the uterotubal junction.

In 1888 Saenger recommended the use of three silkworm sutures through the round ligament and the anterior lamella of the broad ligament bilaterally, near the edge of the uterus, attaching the same to the recti muscles on both sides of the incision. He advises the grasping of a large part of the anterior leaf of the broad ligament to secure a better hold of the uterus without diminishing the mobility of this organ in case of pregnancy.

Some time after his first article on hysterorrhaphy Kelly advised suturing only the ovarian ligament to the anterior abdominal wall for the purpose of gaining a more normal, anteflected position of the uterus without fearing the approximation of the anterior face of the uterus to the abdominal wall. At that time Kelly did not recommend the passing of sutures into the muscular tissue of the fundus. Yet in the present Kelly operation an area of uterine parenchyma is included in the two silk sutures of the peritoneum of the abdominal wall.

I must confess that I am still of the same opinion as Kelly formerly held, that the passing of sutures into the muscular tissue of the fundus, in cases where ventrosuspension is indicated, *i.e.* in the childbearing woman, is altogether objectionable. It does not lie in the power of the surgeon, once he has sutured the fundus, to say whether his operation will turn out to be a ventrosuspension or a ventrofixation. Either he keeps the uterus in contact with the abdominal wall by means of a pessary in the vagina, then in a great many cases he will have a solid fixation instead of his intended suspension; or he allows the uterus to fall back towards the pelvis, drawing the peritoneum into a narrow, funnel-shaped depression. In this way a dead space is created which may be the cause of a suppuration, changing again the suspension into a fixation. Beyea, for this reason, includes a few fibers of the rectus muscle in the sutures, thus obliterating the space between the peritoneum and rectus. Maunsell tries to obliterate the dead space by approximating the sides of the funnel-shaped depression by a few sutures, thus preventing immediate contact of the uterus and the abdominal muscles. But even these modifications cannot entirely prevent the operation from turning out to be a fixation. We simply cannot estimate beforehand the length of the band, be it fibrous or peritoneal, after the stretching has taken place. If it is stretched too far it may in time reproduce the former deformity, especially after a pregnancy, if by good fortune the pregnancy went to full term. On the other hand, if the adhesions remain short, there is the same danger of dystocia as found after fixation. In Kelly's operation, suspending the uterus by the posterior wall to the abdomen, apart from the just-mentioned objections, an unnatural anteflexion is simply substituted for the retroflexion.

Efforts, therefore, have been made to utilize the round ligaments for the correction of the displacement. The round ligament grows *pari passu* with the development of the uterus in pregnancy, and will contract again after delivery, returning to its primitive condition. For that reason Alexander tried to utilize the round ligaments in the operation bearing



his name. But the Alexander operation has several drawbacks. In the first place, he utilizes the distal or weak, attenuated portion of the ligament, which, after stretching, may often lead to the former displacement. Then, the abdomen not being opened, the surgeon is unable to ascertain the condition of

the adnexa. But the most important reason why the Alexander operation never became very popular is the difficulty often met with in finding the round ligament in the inguinal canal. Not very seldom I found the ligament consisting of a few fibers only. Sometimes the ligament at this place is not thicker than a violin string, and surely cannot keep the uterus in the anteverted position. Furthermore, the operation cannot be utilized when the uterus is kept in its retroflected condition by adhesions.

Now, the intraabdominal round ligament suspension of the uterus does away with all these objections. Here the proximal or strong portion of the ligament may be retained as a support; the adhesions, if there be any, can be freed, and the operation does not offer any particular difficulty. Ferguson, with whom the idea originated, and Gilliam, who popularized it, advocate the ventrosuspension by implanting the round ligaments in the abdominal wall. To be sure, I have no substantial objection against this operation except that the slit in the muscle may become the road for a hernia. Yet, whenever I think of this operation the popular version of Goethe's immortal verses comes into my mind:

"Warum in die Ferne schweifen
Siehe das Gute liegt so nahe."

Why increase the difficulties of the operation by implanting the ligaments in the recti muscles, if the simple suturing of the round ligament to the abdominal wall, with only a slight modification of the method originally recommended by Olshausen will do the same service as the complicated Gilliam's operation?

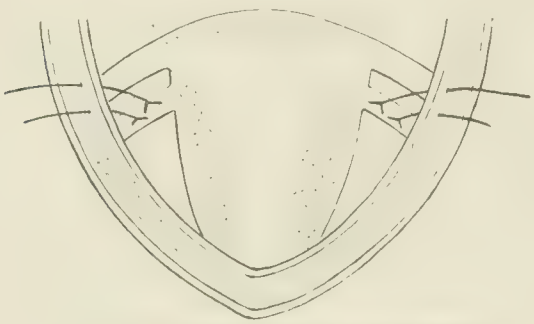


Fig. 1.—Two sutures through each round ligament.

For the last six years the method I adopted of suspending the retroplaced uterus in women of childbearing age is as follows:

The abdominal incision of about 6 cm. is made in the linea alba, beginning immediately above the pubis; the two recti muscles are separated with the fingers, the peritoneum is incised, the uterus located, adhesions, if there be any, freed, and in order to avoid wounding the anterior face which will be for some time in contact with the abdominal wall, the uterus is grasped at its posterior surface by a tenaculum and held in position.

I then try to locate the round ligament. It is easily found in a distance of 4-5 cm. from its insertion into the uterus. While near the uterus the fibers are often scattered and hard to be located; they are united in a single whitish cord that may be recognized through the peritoneal covering at the above-mentioned distance. I grasp, therefore, the round ligament at this point and follow it to the uterus. Here, at its proximal end, I insert the first suture of chromicized catgut and pass the same through the rectus muscle about 2 cm. from the abdominal incision and about 3 cm. above the symphysis. I then insert another suture through the round ligament one centimeter distally from the first and pass it in the same way through the rectus muscle. Both sutures remain for the time being untied until the same procedure is followed on the other side. The sutures are then tied and the abdomen closed.

The second suture marks the only difference between the original method recommended by Olshausen and my modification. Olshausen passes the second, and sometimes a third, suture beneath the round ligament through the anterior lamella of the broad ligament. In this way the uterus is not only suspended by the round, but also by the broad ligament, while in my modification the round ligament, in a distance of one centimeter, the space between the two sutures is the only attachment to the abdominal wall.

After the operation I place a pessary within the vagina to keep the uterus in place. The pessary remains in the vagina until the patient leaves her bed. When the patient is in a vertical position the intraabdominal pressure tends to keep the uterus in the anteverted position.

This is, in short, the method I used for the last six years in a number of cases without a single failure. I was able to follow most of my cases for years, and I always found the uterus in the normal anteverted position, thus affirming Kelly's statement of 1887 that the simple suspension of a large, heavy uterus by means of two ligatures was sufficient to hang it up for a year. Now, while I do not claim for this method any advantage over the Gilliam operation, as far as the results are concerned, I do claim greater facility for its performance.

The uterus in this operation rests in the beginning upon the bladder until the ligaments have somewhat stretched. Yet I never experienced any dysuria in my patients, I suppose for the reason Kelly has given, that the female bladder physiologically expands like a saddle bag, as it has to do in every pregnancy.

As to the possibility of incarceration of the bowels between the uterus and the anterior abdominal wall, I never met with such a mishap, and I regard the possibility as very remote.

Furthermore, this operation in no way causes any impairment of the reproductive capacity of the patient. During pregnancy the ligaments, just as in a normal case, take part in the general hypertrophy of the genital organs, causing no complications of gestation and labor whatsoever. After parturition, involution takes place in the round ligament, just as it does in the other genital organs, and they continue to support the uterus in its normal anteverted position.

The chief advantage of this method is the fact that the operation is universally applicable and entirely satisfactory under all conditions, and that the uterus is placed in the most physiological position, being held forward by its normal supporting structures in the most natural way.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 29, 1906.

THE INNERVATION OF THE UTERUS.

THE last few decades have witnessed remarkable progress in the study of the nervous system, and organs which even a comparatively short time ago were regarded as "nerveless," because no nerve structures could be demonstrated, have been shown by modern histological methods to be plentifully supplied with these elements. Our knowledge of the peripheral nervous system is still far from complete, however, and considerable indefiniteness exists with regard to certain features; thus, what is looked upon as a plexus of nerve fibrils by one investigator is defined as connective tissue by another, and tissue elements interpreted as ganglion cells by one writer are denied any nervous function by another. Not even the gross anatomical relations have been fully determined and explained in certain organs, among which the uterus may be cited as an important example. Anatomists, physiologists, and gynecologists have each in turn endeavored to throw some light on this subject, but unfortunately these efforts have failed in their purpose in most respects. Aside from the purely scientific interest which attaches to a more complete knowledge of the nervous system of the uterus, it has also a practical value, for in this way many questions still unanswered would be finally solved. Among these is the etiology of labor itself, for surely the nervous system must in some manner institute this phenomenon, and the pains are probably the result of nerve stimulation, but of the way in which this is transmitted to the smooth muscle fibers we are almost totally ignorant. Equally important is a more definite knowledge of the nervous connection between the uterus and the ovaries, for the close relation between these two organs undoubtedly depends on a nervous basis. And finally, when we consider the close association between the uterus and the remaining organs in the female subject, a more perfect understanding of the nervous relations would be of untold value. That these relations are not limited to physiological factors, but also include the pathological, is proved by numerous and well-known examples.

Although the course of the nerves outside of the body of the uterus is no longer the subject of controversy, but little is known of their distribution within the tissues of the organ itself. This subject has been made the basis of an investigation in both man and some of the lower animals by Labhart (*Archiv für Gynäkologie*, Vol. 80, No. 1), and the conclusions he presents are worthy of note as a contribution to an important practical matter. The course of the nerve fibers in the uterine tissues, their termination in the myometrium, as well as in the mucous membrane, and the presence of ganglion cells in the substance of the organ, were among the questions which the writer sought to solve. He has not yet accomplished this task, for although his anatomical deductions are of importance they still require to be supported by physiological experiment.

Labhart found in the uterus of the human subject a very complete network of nerves, the larger branches of which are distributed within the middle muscular layer and the smaller divisions around and into the fascicles. He did not succeed, however, in demonstrating satisfactorily the manner in which the nerve elements terminated in the musculature or the endometrium, nor were ganglionic cells found. He thinks that we have no reason to believe an intramural ganglionic system exists in the uterus, as has been claimed by a number of investigators who compared the uterus in this respect to the heart. Uterine contractions from our present knowledge seem to be due to one of two causes; they result from a stimulation of the cervical ganglion or as a reflex originating in some part of the body, including perhaps the uterine wall itself. They may also take place in a myogenous manner, as demonstrated by Kurdinowski on the recently extirpated uterus, in which the thermic and mechanical stimuli probably play a more important rôle than the electrical.

The facts just noted constitute an important contribution to the subject, although it still remains to demonstrate the actual manner in which the nerve fibers terminate and the anatomical relation between the nerve tracts of the uterus, and others in the body. As already noted, physiological tests are necessary to prove these anatomical findings, and these will doubtless soon be forthcoming.

THE TREATMENT OF THE INEBRIATE IN GREAT BRITAIN.

FOR many years the treatment of the inebriate in Great Britain was founded upon the belief that the victim of the habit was wholly responsible for the state in which he found himself, and that the only methods by which dunkenness could be checked were strictly repressive ones. Human interest was almost entirely lacking in the modes of treatment. However, of recent years, a great change has come over the manner in which inebriates are regarded, especially by the medical profession. A striking proof of this alteration is afforded by the report by Dr. Brathwaite, Inspector under the British Inebriates Act, which has just been issued. One point in particular dealt with in the report is worthy of notice, that, according to Dr. Brathwaite's view, while alcoholic excess is a prolific source of disease and of mental instability, disease and mental instability are even more provocative of the alcoholic habit. In fact, that the drunken habits of the people are in the main a result and not a cause of poverty, squalor, disease, and to some extent insanity. Methods which recognize the psychological and neurotic aspects of the question are now in vogue to some extent in Great Britain, and in all respects a very much more intelligent view is being taken of the whole matter of inebriety.

The report draws attention to the fact that the manner in which magistrates in police courts ordi-

narily deal with habitual drunkards is worse than useless as a means of radical cure. The drunkard is subjected either to a fine or to some days' imprisonment, neither of which serves any profitable end. The imprisonment, indeed, not only does not hinder the progress of mental deterioration, which is going on, but hastens it, and the conclusion reached in the report is that the British police-court treatment of habitual inebriates is irrational and inhuman, since it degrades the inebriate and tends to confirm him in his desired impulses and puts a cure beyond all possibility of accomplishment.

Another mode of treatment which has been in use in Great Britain for some years now, is the reformatory system. According to the report this system, as it has been carried out for the past twenty-five years in Great Britain, is too strict and not sufficiently discriminative. The principle appears to have been that inebriates should be practically beyond reform ere the attempt was made to reform them. The segregation of the hopeless and the comparatively hopeful classes of inebriate has been practised in Great Britain only during the past nineteen years, and has not been carried out at any time in a really effective manner.

The most pitiful, and to some extent the most alarming part of the report, is that which relates to women inebriates. These statistics show that women are not only more generally susceptible to alcoholic temptation, but also that they, as a rule, give way to this temptation at an earlier age. The women under detention in British reformatories for their drinking habits far outnumber the male delinquents, the numbers being, in fact, no less than 1,608 women and only 219 men who are inmates of such institutions.

The question of inebriety has been made the subject of discussion in the editorial pages of the MEDICAL RECORD quite frequently. The matter has been treated from many standpoints, and the view has been expressed that it is not wise to press the argument to an extreme point on either side. That alcoholism in some of its forms is a disease seems to have been proven beyond a doubt. It is not merely a vice, but an actual pathological condition of the brain. Whether the taint of alcoholism can be passed down from generation to generation is another matter entirely. Children of alcoholic parents may be and probably will be of a neurotic temperament, whose nerves are easily unstrung and who are apt to look for solace in strong drink. Once the habit is contracted by such as this it quickly develops into a disease. It would seem to be a reasonable view to take that severe treatment is not calculated to cure inebriates of this description. On the other hand, to treat the whole army of drunkards too well might be to place a premium on drunkenness, a result which would be disastrous in every way. The most rational mode of treating inebriates would seem to be to place them under the supervision of a physician, who is versed in psychology, who would decide as to the manner of treatment adapted to their several cases. The old belief, to which so many still cling, that inebriety is, in all instances, a vice which must be suppressed with a strong hand has been demonstrated to be wrong. Besides, it is not workable.

NASAL HEADACHE.

AMONG minor ills there is none productive of greater discomfort to the patient and annoyance to the physician than the symptom or complex of symptoms ordinarily known as a headache, and its treatment has called forth more remedial measures, both ethical and nonethical, than any other common illness. Notwithstanding this fact, its treatment is often a failure, and this can be traced as a general thing to the fact that the remedial measures are directed to the removal of the symptom rather than of the causative disease condition. The vague and uncertain disturbance of the economy commonly termed "biliousness," for want of a better appellation, was for years regarded as the basis for most headaches, but now intestinal toxemia, uricacidemia, eyestrain, and a number of other conditions are looked upon as factors at fault. In an article in the *Glasgow Medical Journal* for November, 1906, W. S. Syme calls attention to the fact that diseases of the nose may also give rise to headaches, and that to this etiological factor an insufficient amount of attention has been given. This may be due to the fact that the study of diseases of the nose is itself of comparatively recent development. And yet, as Syme points out, this organ from its position, its anatomical connections, and its functions, is eminently calculated to give rise, when it is the seat of pathological changes, to the symptom under discussion. For it is an established fact that the nasal cavities are in close proximity to the brain and its membranes; the venous channels of the nose are in direct connection with those inside the cranium, and the same may probably be assumed for the lymphatics; the trifacial nerve, the great sensory nerve of the head and face, is also in intimate relation to the nose or its accessory cavities during a large part of its course.

As all these reasons are active, we may, and actually do have, headache resulting from direct action of nasal disease on the brain and its membranes, headache from irritation of the trifacial nerve or its branches, and lastly, and perhaps most commonly, headache from a disturbance of the function of the nasal mucous membranes or of absorption by the latter of the products of suppuration. Syme quotes a number of instances to illustrate these varieties, and the recital shows very conclusively that a careful study should be made of every case to determine whether the nasal organ is involved in the production of the headache, even when there are no direct symptoms pointing in this direction. Eyestrain is without doubt the most frequent cause of periodical headaches, and probably in ninety per cent. of all such cases the attacks would be prevented entirely if the eyes were fitted with suitable glasses. Nevertheless eyestrain, as even the most enthusiastic partisans are quite ready to concede, is by no means the sole cause, and when its correction fails to remove this symptom other possible exciters of the reflex must be sought. In such case it is well to remember that the nose may be the offending member, and a recognition of the part which this organ may play will, of course, suggest appropriate local treatment, instead of internal medication applied to the relief of the pain.

Fat Necrosis of the Pancreas.

Of the many attempts that have been made to reproduce the lesions of fat necrosis of the pancreas those of Opie have, without doubt, been the most successful. Other observers, by injecting into the pancreas or into its ducts various caustic or irritating substances such as alkalies, acids, turpentine, oil, soaps, etc., have produced alterations more or less closely simulating the clinical picture observed in man, but Opie was able very accurately to reproduce the typical picture by introducing bile, that is, a substance normally present in the alimentary tract, into the pancreatic duct. Inasmuch as this is something that can easily occur in human beings during life Opie's experiments have been accepted as being more likely to afford a correct explanation of the clinical condition than any of those in which the introduction into the organ of large quantities of foreign substances has been necessary. Polya (*Berliner klinische Wochenschrift,* December 3, 1906) acknowledges the acceptability of Opie's theory, but is of the opinion that it is not adequate to explain all of the cases of fat necrosis that occur. Taking as the basis of his experiments the work done by numerous other observers which shows that the pancreatic juice when unmixed with intestinal secretion has little or no proteolytic power, Polya sought to produce fat necrosis in dogs by injecting duodenal secretion and trypsin into the substance of the pancreas or into the duct of Wirsung. It was found possible in all of these ways to produce fat necrosis, but the most successful method proved to be the injection into the pancreatic duct of intestinal juice taken from the duodenum. All seven of the animals that were treated in this way developed fat necrosis, which in one case was so extensive as to involve not only the intra- and retroperitoneal fat tissue, but also the subcutaneous fat of the abdominal wall, of the thighs, and of the pericardium and pleura. The author is therefore of the opinion that the activation of the trypsinogen of the pancreatic juice which occurs when this is mixed with intestinal secretion can cause the lesions of fat necrosis when the mixture is permitted to take place in the substance of the gland. This view has certain attractive features, to be sure, but further work will certainly be necessary to prove that it is more universally applicable than the theory of Opie, for in most of Polya's experiments a certain amount of bile must also have been injected into the pancreas.

Thyroid Grafts.

Although the earlier attempts to secure the permanent growth of transplanted portions of thyroid gland were followed by almost invariable failure several authors, particularly von Eiselsberg and Cristiani, have lately shown that if the necessary conditions are adhered to success can be obtained. These requirements as formulated by Cristiani demand that the bits of transplanted gland tissue be small but numerous, that only the gland of the same species of animal be used, and that the transplanted tissue must be living. To fulfill the latter condition not more than ten seconds must elapse between the moments of excising and implanting the graft. Cristiani and Kummer have recently reported in the *Münchener medizinische Wochenschrift* of December 4, 1906, a case in which not only was a permanent foothold obtained for the transplanted tissue in a case of goiter, but the graft grew *in situ* and produced perfectly normal gland parenchyma. This patient was a woman presenting a parenchymatous goiter of considerable size, in the removal of which it was possible to leave behind only so small a portion of thyroid substance as to give rise to some apprehension that a condition of cachexia strumipriva might result. Accordingly grafts were made and implanted beneath the right acromion process. These maintained their identity and even increased in size, so that at the end of about three years it seemed safe to remove one of them for microscopical examination. It was found that the glandular mass was composed of perfectly normal thyroid parenchyma, and the authors emphasized the fact that the graft was taken from the healthy tissue of a goiter, since this greatly facilitates the practical application of the procedure. Since it appears to be possible to produce new thyroid organs in man which permanently maintain their identity and are able not only to functionate, but even to increase in size, it is not impossible that the method will be found practically available for use in dealing with both myxedema and cretinism, and so effecting a permanent cure of conditions which otherwise demand the continuous and lifelong administration of the specific remedy.

Human and Bovine Tubercle Bacilli.

What appears like a very rational standpoint in regard to the relative positions of these two organisms is taken by Weber (*Deutsche medizinische Wochenschrift,* December 6, 1906), who expresses the following view: Human tuberculosis is, etiologically considered, not an entity, but is the result of two causative agents which are, however, closely related. The tubercle bacilli of the human type are the producers of tuberculosis in man and the organisms of the bovine type give rise to the tuberculosis of cattle. Infection with the bovine bacilli plays but a small part in comparison to the ravages of the human form and occasions only those varieties of tuberculosis, like primary intestinal and mesenteric infections, in which the portal of entry is to be sought in the gastrointestinal canal. This form, furthermore, is of the less importance, as the likelihood of its transmission from one person to another is extremely slight. Still the danger of bovine infection exists, and therefore it is necessary to observe all possible precautions in order to prevent the transmission of the disease from cattle to human beings through foodstuffs, notably milk. It must not be forgotten, however, that when we regard tuberculosis as a popular disease the chief danger comes not from infected cattle, but from tuberculous human beings, for according to our experience it is only man who serves as a source of bacilli of the human type.

The Dissemination of Tuberculosis.

It is a subject of common belief that the expired air of a tuberculous subject contains the active specific germs in sufficient number and degree of virulence to constitute an important factor in the transmission of the disease. In order to test the truth of this fact Huhs (*Zeitschrift für Tuberkulose,* Vol. IX, No. 2) examined a number of cases in the following manner: The patient was directed to breathe directly into the tube of a spirometer, at the end of which was placed a pad of sterile gauze through which the air was necessarily filtered. This gauze under perfectly aseptic precautions was then incorporated in the abdominal cavity of guinea pigs. None of the experimental animals developed any

evidences of tuberculosis, from which it appears that the expired air is free from virulent germs. These observations would seem to show quite conclusively that we have apparently nothing to fear from this quarter, but, as the writer states, increased attention must be given to those sources which have been repeatedly proven to be the active factors in the dissemination of the disease. The most important of these is the sputum, which, in the form of minute infected globules, is scattered broadcast during the act of coughing or sneezing. Prophylactic efforts should therefore be directed mainly to cautioning the patient to keep a handkerchief over the mouth and nose during these acts. If these excretions are then properly disposed of the chances of the patient doing harm to others will be greatly diminished.

Intestinal Absorption.

The results of some interesting experiments on dogs and the human subject on the processes of absorption in the small and large intestine have recently been published by Heile in the *Mitteilungen aus den Grenzgebieten der Medizin und Chirurgie,* Vol. 14, 1906. It was found that the small intestine completely absorbed egg albumin as well as cane and grape sugar, so long as the quantity was sufficient to meet the requirements of the body. When overfeeding is practised, however, a considerable portion of the food passes through into the large intestine without any absorption taking place in the small gut and this likewise occurs in the presence of catarrhal conditions in the latter. As these undigested food masses and certain products of the intestinal secretions pass on into the colon, varying amounts of the digestive enzymes are carried along which probably prepare some of the remaining portions of the food for absorption in the large gut. The large intestine itself is incapable of absorption, Heile maintains, so that rectal enemas containing albuminous materials are practically useless. The absorption of sugar and water from the large intestines is also claimed by the writer to be comparatively slight in amount, a statement which seems contrary to the general idea of this matter.

Anatomy in the Daily Press.

An interesting article entitled "Nature's Patent Office" appeared in the supplement of a recent issue of one of the leading dailies. In it the writer endeavors to show that many mechanical devices which are hailed as new discoveries have already been anticipated in the structure and functions of the human body. But, as so often happens when lay writers discourse on professional topics, some unique information is added. We are informed that the Adam's apple was the first storage cistern ever built, and it works with automatic regularity through health and sickness. It is a most important organ of the body, although for centuries it was considered a superfluous attachment. It regulates the flow of blood between the heart and the brain. When it ceases to operate somebody dies of apoplexy or a rush of blood to the brain. When the heart sends up too much blood to the head the Adam's apple steps in to check the flow and store it up for future emergencies. If the heart is temporarily weakened or put out of good running order the blood stored in this cistern is given up and sent to the brain. The perfect working of this little device is apparent when we consider how comparatively few die of rush of blood to the brain or from a deficiency of supply. We can only add the familiar headline, "Important if True."

News of the Week.

For a National Health Bureau.—Prof. Irving Fisher of Yale University announces that a committee has been formed for the purpose of considering the organization of a national bureau of health and of pushing the matter at Washington. The purpose of the committee is to urge upon the Federal Government the establishment of a national bureau of health to supervise the manufacture, distribution, and sale of food products. Among its members are: President Eliot of Harvard; President Hadley of Yale; Dr. Robert M. O'Reilly, Surgeon-General United States Army; Dr. William H. Welch of Johns Hopkins University; James R. Garfield, Secretary of the Interior; Charles P. Neill, Commissioner of Labor; Dr. Cressy L. Wilbur, chief statistician, vital statistics United States Census; Dr. Thomas Darlington, Health Officer of New York; Dr. Felix Adler, Dr. Daniel C. Gilman, Miss Hazard, president of Wellesley; Booker T. Washington; Dr. Lyman Abbott; Archbishop Ireland; ex-Secretary of the Navy Long, and Andrew Carnegie.

Red Cross Convention and Receipts.—The Senate in executive session on December 19 ratified the new Red Cross convention signed at Geneva by the representatives of most of the powers on July 6 last, providing for an extension of the international agreements regarding the treatment of the wounded and prisoners in warfare. The War Department has completed the auditing of the accounts of the National Red Cross Society for the year ending November 30, 1906. The total receipts for the year were $3,373,237, with a balance in the treasury of $2,381,334. Among the society's collections were $3,090,204 for the California earthquake relief funds, $224,249 for the Japanese famine funds, $12,758.25 for the Vesuvian volcanic disaster fund, and $8,943 for the Valparaiso earthquake disaster fund. A considerable balance of the California relief money is still in the Red Cross treasury, subject to the call of the California Relief Corporation.

Busts of Scientists to be Unveiled.—On December 29 the Board of Trustees of the American Museum of Natural History will hold ceremonies attending the unveiling of the busts of prominent American scientists presented to the museum by Morris K. Jesup. The ceremonies will take place at the museum, Seventy-seventh street and Central Park West, at 3 P.M. Among others addresses will be delivered by Dr. S. Weir Mitchell of Philadelphia on Benjamin Franklin; Baron Speck von Sternburg on Aexander von Humboldt (read by Count Hatzfeldt); Dr. C. Hart Merriam on James Audubon; Dr. Nathaniel L. Britton on John Torrey; Dr. Robert S. Woodward on Joseph Henry; the Rev. Edward Everett Hale on Professor Agassiz; Dr. Arthur Twining Hadley on James Dwight Dana; Dr. Hugh M. Smith on Spencer Fullerton Baird; Dr. William Keith Brooks of Johns Hopkins University on Joseph Leidy, and Dr. Henry Fairfield Osborn on Edward Drinker Cope.

Pasteur's Memory Honored.—According to the *New York Times,* one of the Parisian newspapers recently started a voting contest among its readers to determine the question of "Who is the greatest man in the history of France." At present Pasteur leads the balloting, with 215,725 votes, and behind him in order come, first, Victor Hugo, and, second, Gambetta, while Napoleon is a rather poor fourth, a result gratifying to men of science, but discouraging to conquerors.

Sleeping Sickness.—Prof. Robert Koch, who is at present in the Victoria Nyanza region in Africa studying the nature of trypanosomiasis, in a report to the German Imperial Ministry of the Interior reports great success in the treatment of the disease by means of subcutaneous injections of an arsenic preparation. He states that he has found that the *Glossina palpalis*, a fly which is a source of infection with the trypanosomes of the disease, lives in the undergrowth or water plants at the margin of lakes and feeds on dead water fowl, fish, and crocodiles, especially the latter. Koch availed himself of the offer made by the British Government to place at his disposal an empty mission house at Bougali, Sese Islands, northwestward of Victoria Nyanza, where there are now 900 patients under treatment with subcutaneous injections of the arsenic preparation. He has had patients under observation for two or three months, but on account of fear of relapses concludes that they must remain another two or three months under observation. It is stated that through the ravages of the sleeping sickness the population of the Sese Islands, which in 1902 was 30,000, has been reduced to less than one-half of this number.

Typhoid Epidemic in Scranton.—On one day recently four deaths from typhoid fever and forty-nine new cases of the disease were reported from Scranton, and the total number of cases thus far reported is over two hundred and fifty. It is believed that the water supply of the city is responsible for the epidemic, and the Elmhurst reservoir, which supplies the larger portion of the city, has been closed. All public taps have likewise been shut off. Two attachés of the State Bureau of Health, Dr. A. B. Moulton and F. W. Wetherell, an expert sanitary engineer, are in the city assisting the local authorities.

Model Charity.—At a recent conference with the members of the Illinois State Board of Charities, Governor Deneen outlined a comprehensive plan for placing the State institutions in the first rank. The following recommendations were threshed out and adopted as the program of the administration for the next two years: Model farms supervised by instructors from State Agricultural College, to be installed at every one of the State institutions for the feeble-minded, defective and insane. To abandon the old asylum for the criminal insane at Menard, as unfit for further occupancy. To establish a village of the simple, a segregated colony for improvable epileptics, modeled on those in Belgium. To establish camps for curable consumptives at all the institutions, and one general sanatorium. Appropriation of $15,000 for free distribution of antitoxin. The establishment of a school of psychopathy, at Kankakee, where physicians, beginning with those connected with the State institutions, may be educated in the recognition and care of the insane. All buildings erected in the future are to be fireproof.

Radium Classified as a Chemical Salt.—The disputed point as to the status of radium under the tariff law has been decided by the general appraisers to the effect that radium is a chemical salt, and therefore dutiable at 25 per cent. *ad valorem*. The importers have contended that it should be accorded free entry as a crude mineral, but General Appraiser Wilbur F. Lunt, who wrote the opinion, overrules the protest on the ground that the merchandise is radium bromide, and therefore must be assessed as a chemical salt.

Flat Car Wheels to be Repaired.—As the result of a conference between Dr. Darlington, Health Commissioner, and the officials of the Metropolitan Street Railway the latter have promised to do away with the needless noise occasioned by running cars with flat wheels. Hereafter as soon as a car wheel becomes flattened the car, on reaching the barns, will be fitted with new wheels and the flattened ones will be trued before being put into use again. Experiments are also under way to determine the value of a new steel wheel which it is claimed is less likely to become flattened than those now in use. If the company were to go a step further and replace the noisy and antiquated hand brakes with which the cars are now equipped by the much more efficient pneumatic brake not only would the street traffic be rendered more safe, but another very objectionable element of noise would be removed.

Congress of American Physicians and Surgeons.—The seventh meeting of this Congress will be held in Washington on May 7, 8 and 9, 1907, under the presidency of Dr. Reginald H. Fitz of Boston. On Tuesday, May 7, the subject for discussion will be "The Historical Development and Relative Value of Laboratory and Clinical Methods in Diagnosis." The president's address will be delivered in the evening of that day. On May 8 the subject for discussion will be "The Comparative Value of the Medical and Surgical Treatment of the Immediate and Remote Results of Ulcer of the Stomach."

Johnson County (Ia.) Medical Association.—The following officers were elected for the ensuing year at the recent meeting of this society: *President*, Dr. Henry Albert; *Vice-President*, Dr. Laura H. Branson; *Secretary and Treasurer*, Dr. J. A. Valenta.

Buchanan County (Mo.) Medical Society.—At its recent meeting this society elected the following officers: *President*, Dr. O. B. Gleaves; *Vice-Presidents*, Dr. S. F. Kessler, and Dr. W. J. McGill; *Secretary*, Dr. C. W. Fassett; *Treasurer*, Dr. J. M. Bell.

New York Academy of Sciences.—At the annual dinner of the New York Academy of Sciences an address was delivered by Dr. N. L. Britton, on "Considerations and Illustrations of Color in Plants." These officers were elected: *President*, Dr. N. R. Britton, Director of the Bronx Botanical Garden; *Secretary*, Dr. E. O. Hovey, Curator of the American Museum of Natural History; *Treasurer*, Emerson McMillin; *Editor*, Prof. E. L. Poor of Columbia University.

Newton County (Miss.) Medical Society.—The following were elected as officers at the recent meeting of this organization, held in Newton: *President*, Dr. J. B. Bailey, Conehatta; *Vice-President*, Newton county, S. B. Henton; *Vice-Pesident*, Neshoba county, D. J. Rush; *Secretary and Treasurer*, W. J. Chapman, Newton.

St. John (N. B.) Medical Society.—At the recent meeting of this society officers were elected as follows: *President*, Dr. Thos. Walker; *Vice-President*, Dr. Jas. Christie; *Secretaries*, Dr. Warwick and Dr. J. H. Scammell; *Treasurer*, Dr. J. R. McIntosh.

St. Louis County (Mo.) Medical Society.—Officers were elected as follows at the recent meeting of this society: *President*, Dr. F. E. Guibor of Maplewood; *Vice-President*, Dr. O. J. Jensen, Florissant; *Secretary and Treasurer*, Dr. W. R. Moore, Central.

Morgan County (Ill.) Medical Society.—At a recent meeting held in Jacksonville the following officers were elected for this society: *President,* Dr. E. L. Crouch; *Vice-President,* Dr. H. C. Woltman; *Secretary,* Dr. Allen King; *Treasurer,* Dr. E. F. Baker.

The Alumni Association of the German Hospital in the city of New York will hold its tenth annual banquet at the Café Martin, on Saturday evening, December 29, 1906.

Northern Tri-State Medical Association.—The thirty-fourth semiannual meeting of this organization will be held at Elkhart, Ind., on January 8, 1907. The president is Dr. Charles D. Aaron of Detroit and the secretary is Dr. Wm. F. Shumaker of Butler.

In Honor of Dr. Mary Putnam Jacobi.—Under the auspices of the Women's Medical Association of New York City a memorial meeting is to be held at the Academy of Medicine on the evening of January 4, 1907, as a tribute to the late Dr. Mary Putnam Jacobi. Addresses will be delivered by Dr. William Osler, Dr. Elizabeth Cushier, Prof. Felix Adler, Mrs. Florence Kelley, Dr. Charles L. Dana, Mr. Richard Watson Gilder, and Dr. Annie S. Daniel.

The Late Dr. W. K. Otis.—At the regular meeting of the Second Section of the American Urological Association, held in New York on Wednesday, October 24, 1906, the committee appointed to prepare a memorial on the death of Dr. W. K. Otis presented the following:

"The ties of lifelong intimacy which bound most of us to Dr. Otis, make his death a subject of grief to each individual. The usual set form of preamble and resolutions, therefore, were deemed inadequate by your committee to express our sorrow. "Billy's" demise is, to the older members of the association as if a much loved brother had gone from us. Your committee begs to submit:

William Kelly Otis' earthly career ended on September 22, 1906.

To the members of the American Urological Association, his death is a threefold blow.

Most of us knew him intimately from his childhood; by his decease we lose a consistent friend, a charming companion, a most estimable colleague.

To the Science of Urology his death means an irreparable loss. Cut off in the midst of his career, his inventive genius is stopped; the new and useful instruments he was continually devising must now be perfected by other hands. The advances in our work, he can no longer aid in developing.

The American Urological Association loses one of its founders, one of its most active coadjutors, one of its truest adherents.

Our association shares with the family of William K. Otis, with the profession at large, and with that world in which true manhood is understood and appreciated, that deep grief which the death of so noble a character inspires.

[Signed] Ramón Guiteras,
A. Ernest Gallant,
Ferd. C. Valentine,
Committee.

The Late Dr. William P. Brandegee.—The following resolutions on the death of Dr. William P. Brandegee were passed at an executive meeting of the Otological Section of the New York Academy of Medicine, on Thursday, December 13, 1906:

Whereas: Death has suddenly taken from us, in the prime of his life, our colleague, Dr. William P. Brandegee, a member of this Section, and one of its most faithful and enthusiastic supporters; and

Whereas: By his unselfish devotion to duty, and his professional ability, he has won the respect and admiration of all who were privileged to know him; therefore be it

Resolved: That in the death of Dr. Brandegee this Section has sustained the loss of one of its most valued members, whose personal character and professional career must remain a lasting stimulus to the highest and best aims of his colleagues.

Resolved: That our profound sympathy and condolence be, and hereby are, offered to the bereaved widow and family, and that a copy of these Resolutions be presented to them.

Resolved: That these Resolutions be inserted in the Minutes of this Section, and that a copy be sent to the Medical Record, and the *N. Y. Medical Journal* for publication.

[Signed] Dr. James F. McKernon,
Dr. John D. Tichards,
Dr. Joseph A. Kenefick,
Committee.

Dr. Emil Gruening, *Chairman.*

Obituary Notes.—Dr. William Herbst of Trexlertown, Pa., died December 22 at the age of seventy-three years. He was graduated from Jefferson Medical College in the class of 1855. He was well known as a botanist and for several years was professor of botany at Mühlenberg College.

Dr. Charles C. Odlin of Melrose, Mass., died on December 19 at the age of sixty years. He was one of the founders of the Melrose Hospital and was at one time president of the Massachusetts Medical Society.

Dr. Samantha Nivison of Hammonton, N. J., died on December 19. She was born in Mecklenburg, N. Y., in 1833 and received her medical degree from the Women's Medical College of Philadelphia in 1856. In 1862 she opened a sanatorium at Dryden, N. Y., and later also conducted a similar institution in Hammonton.

Dr. J. R. Coleman of Paducah, Ky., died on December 12 of nephritis at the age of forty-six years. He was graduated from the medical department of the University of Louisville in 1883 and had practised in Paducah for six years. He was at one time vice-president of the Southwest Kentucky Medical Society, and also of the West Tennessee Medical Association, and had been president of the Caloway County Medical Association and of the McCracken County Medical Association.

Dr. George M. Emrich of Chicago died on December 12 of acute nephritis. He was born in Brockville, Ill., 1853, and was graduated from the Chicago Medical College in 1873. He retired from active practice in 1893.

Dr. R. D. Clarke of Akron, Ia., died on December 10 at the age of sixty-four years. Dr. Clarke was born in Cortland County, N. Y., but his family soon removed to Wisconsin. He served in Company K Wisconsin regular infantry during the Civil War. He received his medical degree from Rush Medical College and had practised in Akron since 1867.

Dr. John R. Leigh of Clarksville, Va., died on December 12 at an advanced age. He was one of the best known physicians in his county and had been an active practitioner for over sixty years. He served with distinction in the Civil War.

Dr. Joseph H. Firestone of Freeport, Ill., died on December 14 of typhoid fever. He was born at Fredericksburg, O., in 1862, and was graduated from the Northwestern University of Chicago in 1897, since which time he had practised in Freeport.

Dr. Walter D. Clement of Toronto, Ont., died on December 11 at the age of seventy-six years. He had practised in Oxford County for forty years, beginning in Innerkip at the age of twenty-four and remaining there until thirteen years ago, when he moved to Woodstock. About three years ago he gave up active work and moved to Toronto.

Dr. Edward D. Cherry of Marboro, Va., died on December 16 at the age of eighty-three years. He was for many years one of the best known physicians in the county, but retired from practice some time ago.

Dr. Jeremiah R. Levan died at Philadelphia on December 17 at the age of seventy years. He was graduated from the medical department of the University of Pennsylvania in the class of 1861. He was medical director of the Fidelity Mutual Life Insurance Company.

Correspondence.

PROSTATECTOMY IN TWO STAGES.

To the Editor of the Medical Record:

Sir:—I notice in your issue of November 24 an editorial note upon my article in *The Annals of Surgery* on "Prostatectomy in Two Stages," and in the later issue of December 8, a letter from Dr. Howard Lilienthal claiming priority in the two-stage operation for the removal of the hypertrophied prostate.

I desire to answer this letter in the same spirit in which it was written, and to submit some other facts bearing upon the matter in question. In the first place I would call attention to the opening paragraph of my article, which reads: "It is not the object of this brief communication to present a novel operative technique or original method, but it is simply an observation of personal work performed in the past year, etc."

There is, therefore, no intention on the writer's part to claim priority. The work reported was confined to that of the *previous year*. I had, for several years, deliberately operated in two stages in similar cases, although I had never reported upon it, and I have not yet been able to find the date of my first operation.

In any case, I would call attention to the fact that Dr. Samuel Alexander wrote a paper (December 12, 1896) about ten years before the appearance of Dr. Lilienthal's paper, in which he calls attention to the advantage of preliminary perineal drainage prior to performing a complete prostatectomy, and, in this article, reports a case obviously operated upon some time before the date of publication. In a personal letter to me Dr. Alexander states that the value of perineal drainage in these cases he learned in 1883.

There is no intent on my part to disregard the work of Dr. Lilienthal along the same lines; and, had I known that there would be found in my paper any suggestion of a claim to priority, I would have stated these facts at the time of writing.

Charles H. Chetwood, M.D.
109 East Thirty-fourth Street, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—HOSPITAL MANAGEMENT—ANEURYSM OF THE NECK—SARCOMA—CEREBRAL HEMORRHAGE—FAT NECROSIS—EXTERNAL VERSION—THE UNIVERSITY AND MEDICAL SCHOOLS—LUNACY.

London, December 7, 1906.

This is the last day for sending in voting papers for the election of three direct representatives on the General Medical Council. Some people think the vote will be made larger than usual, but those who have spoken to me about it seem very apathetic. The British Medical Association is of course trying to return its own nominees. One point against them is that they favor the notion of an annual impost on practitioners to keep up the Council. Many are not aware of this, but as soon as it is mentioned express opposition and even indignation. When hundreds find it so hard to get a livelihood it does seem too bad for their richer brethren to propose a tax on behalf of a Council that has never given satisfaction. Three other candidates unite on the plea that only a general practitioner ought to be chosen. There have been good general practitioners on the Council, but none of them, perhaps not all together, have done as good work there as Sir Victor Horsley—so the argument does not seem much. It was used, however, against one of the best candidates (who has withdrawn), although he had been some thirteen or fourteen years in actual general practice and fought the best battle against contract work before he became a consultant.

The session of the Council was concluded last week. The proposal to increase the number of direct representatives was again outvoted. The fact is this direct representation has proved useless and was a blunder at the time, stimulated by the British Medical Association in the hope of controlling it. Indirect representation was urged by others, that is that each corporation should give the voting to the members and not to its ruling committee. That would have been a real reform.

Yesterday Sir William Church presided at the conference on hospital administration. A scheme of twenty-five clauses intended to serve as model principles of hospital management had been drawn up, and it was actually proposed that the whole should be accepted *en bloc*—a plan wholly worthy of the methods of the British Medical Association, which so often succeed in stifling discussion. But before this course was moved Sir William Church spoke and especially enforced the opposition of the profession to the abuse of the out-patient department. He showed how that side of hospital work had gradually increased, and said that in 1682 the authorities of St. Bartholomews had complained of its cost, though at that time the patients must have been insignificant in number. Originally out-patients were confined to those who had been treated in the wards. Now every one fancied he had a right to such relief, and it was given to the great injury of the profession.

Sir H. Burdett then moved a general approval of the principles formulated by the joint committee, remarking that medical men insisted on a reduction in free treatment; it was certain some who received it could afford to pay for it. Hospitals had become desirable places of residence in illness. The poor looked on disease as only to be removed by drugs, and some mothers brought children for these when they only needed to be washed and fed. He advocated the establishment of provident dispensaries throughout the country.

The motion was seconded by Dr. Pope, who was followed by a number of speakers, who objected to vote on a series of recommendations as a whole, some clauses being objected to by some and others by other speakers and some being inconsistent with the institutions they represented. Thus Mr. Harben of St. Mary's Hospital desired the omission of the restriction on pay-wards. It was further proposed to omit the clauses which applied to the medical staffs as distinguished from lay-governors of hospitals. The clause, recommending the abolition of subscribers' letters of recommendation, was also objected to. Then an amendment was moved that the clauses be separately discussed, and this was supported by several speakers. The Chairman suggested the adoption of the general principles, but it was said this would lead to no action, and eventually it was agreed to appoint a committee to report further and to hold a conference annually.

At the Medical Society of London on the 26th inst., Mr. J. Berry related a case of large arteriovenous aneurysm of the neck in a young girl. It was as large as the fist and produced dyspnea, hoarseness, and palpitation. All the deep and most of the superficial veins of the right anterior and posterior triangles seemed to be involved; but on operating the main trunk of the internal jugular and the common carotid were not involved. The sternomastoid was divided, and the tumor dissected out. It was suggested that cricoid aneurysm of the scalp of traumatic origin might be composed of dilated, thickened, tortuous veins. As to this the President (Mr. Ballance) described cases which he believed were arterial, but in others he thought they might be both arterial and venous. Mr. Wallace said when veins and arteries communicated in the neck there was greater venous dilatation than elsewhere, *e.g.* the popliteal space. Mr. Spencer considered cricoid aneurysms of the scalp were arterial.

A case of sarcoma in the pterygoid region in a man of thirty was then described by Mr. G. W. Spencer. The tumor protruded behind and below the ramus of the inferior maxilla and also inward so far as to nearly close the fauces. Dyspnea, dysphagia, and insomnia were distressing. The tumor was encapsulated as was shown by mobility of the superficial structures and absence of glandular enlargement, as well as by the mucous membrane gliding freely over it, with no sign of induration or ulceration. A horizontal incision was made below the jaw and the tumor shelled out, and proved to be a fibrosarcoma. There was no hemorrhage and the pharynx was not perforated. Seen six months afterwards there was nothing abnormal but the linear scar. A similar case was described by Patrick Heron Watson, in 1869, who shelled out the tumor

through a free incision penetrating the mouth. Another was also removed by Sir F. Semon from the side of the pharynx. The patient had worn a tracheotomy tube for several years.

At the Clinical Society Dr. Walter Carr read an account of a case of hemorrhage into the prefrontal lobes which well illustrated the difficulties of diagnosis in such lesions. Diabetic coma, uremic coma, or apoplexy might have accounted for the case, and only at post mortem was its true nature shown. A small saccular aneurysm was found on the anterior communicating artery, and rupture had occurred into the left prefrontal lobe, the hemorrhage extending into the right lobe, probably only a short time before death. The patient had been admitted in a semicomatose state seven hours after sudden unconsciousness had set in. There was albumin and sugar in the urine. The aspect was not that of diabetic coma. In two or three days consciousness returned, but on the seventh day drowsiness appeared, temperature rose, and he died on the ninth day, comatose. The case shows that a small hemorrhage into the prefrontal lobe may be followed by recovery, having given no indication of so serious a lesion. This view is supported by a similar case mentioned by Dr. A. E. Garrod, when the patient died of a second attack, the first one having left a clot found at the post mortem.

Dr. J. Fawcett read a paper on acute peritonitis with fat necrosis, but no disease of the pancreas. At a laparotomy nothing was found except areas of fat necrosis on the great omentum and a little extravasated blood. Death occurred next day. No abnormal change was found in the pancreas, even under the microscope. Cultivations from the spleen and blood from the right heart gave pure growth of *Bacillus coli communis*. Most such cases are associated with pancreatic disease, but three others were reported from Guy's records of the last six years, though in none was the microscope used. The President, Mr. Clutton, thought we could not at present explain the presence and absence of fat necrosis, and said that in some cases of slight injury in which laparotomy had been done, extensive necrosis had been found and recovery followed.

Mr. Feddon related a similar case in which he found a brown fluid in the abdomen and the patient recovered. Mr. Spencer suggested the possible presence of accessory lobules of the pancreas. Dr. Bosanquet suggested a small hemorrhage at the border, and in support of this observed that hemorrhage rather than inflammation was the primary lesion in many cases, especially when fat necrosis and pancreatitis coexisted.

The Obstetrical Society discussed last month the methods of external version apropos of a paper by Dr. Rivers Pollock, who reported fifteen cases. He advocated suspension of the patient by the feet nearly or quite in the vertical position, a plan old enough, for Hippocrates recommended something of the kind. This position, Dr. Pollock said, led to disengagement of the breech from the brim, and it could be prevented from descending again by pressure, and the patient could then be placed on her back and the version completed. Dr. Champneys said the position of the legs was not important; it was the trunk and especially the pelvis which mattered. In the erect position the brim of the pelvis was inclined to the horizon at an angle of about 60 degrees. In the inverted position the angle would be the same. In the genupectoral position, properly arranged, it would be pointed vertically downwards. Could the inverted position be better? Dr. Herman said that in the Trendelenburg position the long axis of the uterus was horizontal. Dr. Herbert Spencer said that at about seven and a half months the operation was easy and could be done in a few seconds with the patient in the dorsal position. Later it became increasingly difficult, and was usually impossible at term or during labor. Raising the pelvis seemed likely to facilitate external version, but none of the cases related were at term, and it was then or in labor that difficulty was experienced. Dr. Williamson said he had tried the method in a modified form in a breech case. He could not dislodge it from the brim in the dorsal position, and then tried the Trendelenburg position over the back of a chair, when version was easy. A fortnight afterwards labor took place with a vertex presentation. Dr. Nepean Longridge had often done external version in breech cases; in three he tried the Trendelenburg position. He asked whether in the vertical position artificial liquor amnii might be poured into the uterus in cases in which the natural fluid had drained away. Dr. Pollock, in his reply, said he had tried the genupectoral position in one case, but the child was not disengaged from the brim, and it was not easy to reach it and push it towards the fundus.

Sir Arthur Rücker distributed the prizes at Charing Cross School on Wednesday and took the opportunity of telling the students that the relations of the London University to the medical schools are now much the same as those which subsist between the colleges and universities of Oxford and Cambridge. He was glad there had never been any friction between the schools and the university, which was not only a going but a growing concern. It had now 3,000 internal students and 8,000 other students. In the past five years its income had increased from £29,000 to £95,000.

The London Hospital has received £5,000 from Mr. J. A. Fielden, completing his gift of £32,000 providing an isolation block of eighty beds for infectious cases.

Yesterday Sir J. Crichton-Browne, who has been a Lord Chancellor's Visitor in Lunacy since 1875, gave evidence before the Royal Commission. He said the flagrant abuses and cruelties that formerly existed had been abolished by the vigilant supervision of the commissioners on lunacy, but that board was terribly overworked and the work must go on increasing. He did not believe the addition of the chancery visitors would relieve them. It would be a public calamity and a grievous wrong to the insane to interfere with the jurisdiction of the commissioners. It was a moot question whether insanity was increasing out of proportion to population; he inclined to think it was. Insanity was not one well-defined disease, but a group with nebulous margins, and it might be that the mass was expanding in one direction and contracting in another. Even if the increase was exactly in proportion to population that would not be satisfactory, for our civilization could not be of the right sort if we were carrying our diseases and infirmities with us. He looked to the time when the Board of Commissioners should be an integral part of a Board of Health, presided over by a cabinet minister. Meantime it was urgently needed to reinforce the commissioners. He suggested, inter alia, two additional members and a paid chairman of distinguished position.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

BRONCHOSCOPY—CIRCULATION IN THE EXTREMITIES—OSSIFYING MYOSITIS—PERFORATING GASTRIC ULCER—PUBIOTOMY—FAT NECROSIS.

VIENNA, November 25, 1906.

PROFESSOR HERMANN VON SCHRÖTTER recently performed the operation of bronchoscopy under conditions of unusual difficulty. The patient was an infant of eight months, suffering from the impaction of a spicule of bone which had penetrated into the right bronchus. The little patient had been brought into Escherich's clinic suffering from extreme dyspnea and v. Schrötter was called in as consultant. It was found that the right side of the thorax exhibited no respiratory movement whatever, and the diagnosis of foreign body in the air passages was made. On attempting to introduce a bronchoscope for the purpose of ascertaining the position of the obstruction v. Schrötter found that no instrument sufficiently small was available. A special tube with a diameter of only 3.5 mm. had to be made, but was furnished by the instrument maker the next day. By means of this instrument v. Schrötter was able to discover the body and to seize it with a suitable forceps. On attempting to withdraw it, however, it was discovered that the object was too large to pass through the lumen of the tube and the operator decided to remove the bronchoscope, together with the forceps and the foreign body. In doing this so much force was necessary that it seemed more than probable that serious injury to the air passages must have resulted, but this turned out not to have been the case. The infant immediately began to breathe freely and had soon recovered completely. The object removed was found to be a particle of bone 1.5 cm. long which the child had gotten into its mouth from a sausage that it had been sucking. The operation was performed without anesthesia.

A procedure for the purpose of ascertaining in cases of gangrene of the foot at what point the circulation is interrupted was demonstrated by Moszkowicz before the Gesellschaft der Aerzte. One patient was a waiter of sixty-seven years, who suffered from intermittent claudication. The second patient was a thirty-seven year old cobbler who had lost his fourth and fifth toes on the left side through gangrene attending Raynaud's disease. The test is performed by elevating the extremity for a short time and then applying a rubber bandage to the thigh sufficiently tight to produce complete anemia of the limb. After about five minutes the bandage is released. In a normal leg the circulation reappears instantly, but this does not occur in patients suffering circulatory disorders. In the patient with Raynaud's disease the cutaneous flush appeared quickly in the thigh, but did not at first proceed beyond the knee. In the course of a minute or two it could be seen gradually creeping down to the toes, until finally the circulation was restored in these also. The other patient manifested this delay in the restoration of the blood flow to a much less

degree, and in three cases of gangrene of the foot it could be observed that the flushing became checked at a definite line of demarcation and did not proceed beyond this point. The symptom was so pronounced that the speaker believed that by this means it was possible to determine at what level amputation should be done in cases of gangrene. In cases in which the circulation was only impeded, but not completely interrupted, the symptom could be used as a differential test, and the speaker also suggested that possibly its frequent repetition might favor the development of a collateral circulation.

A case of the unusual disease, progressive ossifying myositis, has been reported by Gustav Singer. Since the middle of the last century only sixty-six cases have been described and the present one is only the second observed in Austro-Hungary. The patient was a boy four years old who, since the age of eighteen months, had had bony growths develop in the various muscles. The muscles of the neck and upper back had been transformed into a rigid cuirass, rendering the head immovable. The muscles of expression and of mastication were not involved, but those of the back and thorax were ossified to a considerable degree and respiration was abdominal. The flexor muscles of the upper arm were converted into a thick plate of bone and the member was fixed to the trunk through the ossified fibers of the latissimus dorsi and pectoralis major. The muscles of the forearm and of the hand were not involved. The abdominal muscles were permeated by a recticulum of bony strands, but the glutei and the lower extremities were free from change.

Prof. Schnitzler has successfully operated on two patients suffering from perforation of gastric ulcers into the free abdominal cavity. One of these cases was particularly interesting, since the patient had already recovered from a similar perforation. While on the one hand this may be regarded as an instance of the effectiveness of modern surgery, on the other hand it is instructive since the second perforation occurred a year after a gastroenterostomy performed for the relief of the peptic ulcer. Schnitzler stated that recurrences of ulcer after gastroenterostomy, no matter how performed, occurred so frequently that the operation could no longer be regarded as a curative procedure. When stenosis was present, of course, the operation was justified or demanded, but in dealing with cases of simple ulceration without mechanical disturbances operative treatment was indicated only when persistent internal treatment had been without effect.

Heinrich Rotter has reported a case of pubiotomy which he considers is an argument in favor of the operation. The woman was a VI-para, but only the third child was born alive. She was only 145 cm. in height and presented evidences of early rickets. The anterior superior spines measured 25 cm., the iliac crests 27.5 cm., the external conjugates 17 cm. The woman desired a living child, and since she had had one spontaneous labor she was allowed to go to term. Pubiotomy was deemed the most suitable procedure, and by this means a living child was easily delivered with forceps. The child weighed 3,700 gm., and was 52 cm. in length. The pelvis was first encircled by a binder, but from the second to the eighth day was held together by adhesive straps. The legs were kept bandaged together till the eighteenth day. The incisions healed by first intention, the gait is perfect, and bony repair has taken place without any considerable amount of callus formation.

A case of fat necrosis has been reported by Sigmund Fuchs. The patient was a very stout woman of fifty-three years, who suddenly began to have severe pain in the upper part of the abdomen, accompanied by vomiting. Sugar and acetone were found in the urine, and on the forty-seventh day of the disease she died in coma. At the autopsy the diagnosis of fat necrosis was confirmed, and it was found that only the head of the pancreas still remained. The abscess resulting from the necrosis had ruptured into the stomach and given rise to metastases in the lung.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

NEW MEDICAL SCHOOL—LEPROSY IN A WHITE MAN—X-RAY TREATMENT OF LEPROSY—THE CHOLERA SITUATION.

MANILA, November 1, 19—

THE new Philippines Medical School, provision for which was made by Act of the Commission some months ago, is gradually assuming definite shape. The Board of Control has named the following persons as members of the faculty: For the Chair of Chemistry, Prof. Paul C. Freer, formerly of Michigan University; Chair of Pathology, Dr. Harry T. Marshall, formerly of Johns Hopkins University; Chair of Tropical Medicine, Dr. Richard P. Strong, of the Bureau of Science; Chair of Surgery, Dr. John R. McDill, formerly assistant to Dr. Nicholas Senn, now surgeon-in-chief of the St. Paul's Hospital, Manila; Chair of Hygiene and Public Health, Dr. Victor G. Heiser, P. A. Surgeon, Public Health and Marine Hospital Service, Director of Health; Chair of Medical Jurisprudence, Dr. Ariston Bautista Lim; and Chair of History of Medicine, Dr. José Albert. Soon after these gentlemen were named a meeting was held and Dr. Paul C. Freer was chosen dean of the faculty. It is hoped that the school will be open and ready to receive students at the beginning of the next scholastic year, which will be about the first of June. It is intended to procure the services of competent persons, from either the United States or Europe, to teach the subjects of anatomy and physiology. No separate building is yet available, but with the facilities of the Bureau of Education and of the new Civil Hospital, at the disposal of the Medical School, it is thought that there will be ample accommodation for the first few years. Especial care will be taken to make the course as practical as possible, and in order to do this five full years will be necessary before graduation.

With the exception of a soldier of the United States Army, who is now being cared for at Fort Screven, and who is supposed to have contracted leprosy in the Philippine Islands, the first case of leprosy known to have occurred in a white man in the Philippines was detected a few weeks ago in the person of G. P., who was employed as a clerk in the Insular Custom House. He was born in Germany in 1864, but lived in the United States for a few years prior to his coming to the Philippines. He has been a resident in the islands during the past six years. He was said to have been a man of temperate habits, with the exception of drinking a large quantity of beer daily, but not sufficient to produce intoxication.

There is not much light upon the manner in which he might have contracted the disease. During the past year he made his home with a respectable family, and so far as known no leper servants or others were known to be about the house. About two years ago, while a resident in the provinces, it is said he lived with a native woman as his mistress. Investigation is now being made in order to determine whether this woman had leprosy.

During the past year he had been complaining of symptoms similar to those of rheumatism, complaining more particularly of ill-defined pains in the feet and legs. He was given the ordinary rheumatic treatment, and while the symptoms seemed to disappear, he did not seem to derive much permanent benefit. About a month ago he became afflicted with a skin eruption, particularly about the face, which partook of the nature of hyperemia. The attending physician became suspicious and had skin scrapings taken which were examined microscopically and found to contain numerous leprosy bacilli. A number of microscopic examinations were made subsequently, and the leprosy bacilli were found in each instance. He was immediately removed to the San Lazaro Hospital, and after confinement at that institution for about ten days he suddenly died. At the time of his admission to the hospital there were no particular symptoms which indicated to the attending physicians that sudden death was to be expected. Up to 6 P. M. upon the day of his death he seemed to be in his usual condition. About 9 P. M. he complained of being unable to sleep, and requested a sleeping powder. He was given ten grains of trional. At 11 P. M. he was found dead in bed by an attendant. The postmortem examination which was made the next day showed that he had a dilated heart and a slight cirrhosis of the liver. No drugs or other substances were found in the stomach which would indicate self-destruction; in fact, it has not yet been satisfactorily determined what was the cause of death.

The new *x*-ray apparatus for the San Lazaro Hospital has now been installed, and the resumption of the treatment of lepers by the *x*-ray will be immediately begun. The two cases which have been mentioned heretofore, from time to time, and which were cured and remained so for a period of about nine months and then relapsed, will be again subjected to treatment.

There has been a great improvement in the cholera situation in the Island of Luzon. During the past week there have been only eight cases, as against several hundred a few weeks ago. In the City of Manila there has not been a single case reported for a whole week. In the province of Iloilo, on the Island of Panay, the situation is not so encouraging. The Bureau of Health reports that for the week ending October 27 there were 630 cases and 480 deaths. The health officials are almost powerless to accomplish anything owing to the belief of the masses that the disease is not cholera, and their consequent indifference to complying with the measures that are recommended for its eradication. During the past week, in some sections of this afflicted province, the preventive measures have received another setback, owing to a widely-circulated rumor that the Government officials were purposely distributing the disease in order to lessen the number of people.

It would scarcely seem possible that such stories should be given credence, yet such is the case. It is said that the origin of this rumor was due to the vaccination against smallpox which was recently commenced in that province by the Bureau of Health.

Progress of Medical Science.

New York Medical Journal, December 15, 1906.

Unusual Suppression of Urine.—H. D. Howe reports a case, his patient being a woman, age not given. She passed no urine for a period of twenty-five days, and died from anemia. There was no coma, and there were no general convulsions, though twitching and local spasms were frequent. The anemia was referred to a hydronephrosis following on blocking of the ureters with a carcinomatous deposit. Autopsy showed the left kidney to be a mere thin-walled cyst, containing about ten ounces of clear fluid. The thick abdominal walls, the thinness of the cyst walls, and its situation beneath the ribs, were the evident reasons for its being overlooked. There was no macroscopic evidence of kidney structure. The ureter was obliterated at the pelvic brim by a carcinomatous mass, originating from the stump of the broad ligament and involving the sigmoid and rectum. The right kidney showed true hypertrophy of the kidney structure, as well as great dilatation of the pelvis. It measured ten inches in length, four and a half wide and three thick, and contained nearly a pint of urine. There was a small carcinomatous involvement of the lower portion. As on the left, the ureter was entirely obliterated by a carcinomatous mass arising from the stump of the right broad ligament.

The Role of the Blood in Nutrition and Repair.—J. P. Arnold refers to the circulatory apparatus in some of the lower orders of life, noting that each body cell, except in the spleen, lies in a pool of lymph to all intents and purposes just as an ameba lies on the water. The products of digestion, the nutritive dextrose, fats, etc., together with water, salts, and oxygen, eventually reach the capillaries, and pass out through the stomata between their epithelial lining cells into the pericellular lymph spaces. The serum albumin and globulin, as well as the fibrinogen, pass out in the same way (osmosis), though less readily on account of the size of their molecules. From these substances added to the lymph, each cell takes up its own required nutritive material. The cell-waste is excreted into the lymph and carried away, although water, salts and carbonic acid gas are also carried away by the veins. Hence the cells live not in stagnant pools, but in a constantly changing lymph stream. Consequently, no cell in the body can be sick or diseased if it is supplied with the proper quantity and quality of lymph and has its waste products properly removed, excepting of course the results of injuries. As the proper quantity and quality of lymph depend upon the quality and quantity of blood, the conclusion may be stated as follows: No cell can be sick or diseased, except as the result of direct injury, if it be supplied with the proper quality and quantity of blood, and have its waste products properly removed. Even the result of direct injury may be brought within this conclusion, for an injury immediately alters the quality and quantity of blood in the injured part. The regulation of the proper amount of lymph is under the control of the vasomotor system. The quantity may be abnormally low from general loss of blood or from diminution of local supply from vasoconstriction or pressure. It may be abnormally high from plethora or excessive amount in localized areas from active vasodilatation or to the obstruction of the outflow through the veins and lymphatics. The quality may be abnormal from ingestion of poisons or improper foods, improper digestion, bad air, bacterial infections, failure of elimination organs, failure of the liver to destroy certain poisonous materials absorbed from the intestines, and to convert uric acid and other kindred waste products into urea or from failure upon the part of the ductless glands to properly elaborate their own characteristic secretions.

Aortic Aneurysm Treated by Introduction of Fifteen Feet of Silver Wire; Death After Four Months.—The salient points in the case reported by J. R. Eastman are embraced in the title of his paper. The patient was a male negro of forty-one years, who denied any specific infection. Full details of findings of physical examination are given. The wire was introduced through a fine trochar without anesthesia into a pulsating tumor in the fifth interspace to the right of the sternum, the trochar being passed directly backward for two and one-half inches, its proximal end being anchored to the skin by strapping. The introduction of the wire seemed to make the patient's pain worse, and three weeks later five feet of the wire were withdrawn. Orthopnea developed and gradually increased. The patient died at stool, death being accompanied by profuse hemorrhage from the mouth. Autopsy revealed a sudden dilatation of the aorta one inch from the heart. This dilatation practically involved the whole arch or the vessel and lung below the level of the arch, filling the space between the descending portion and the heart. At the point of exit of the aorta from the mass which was slightly above and to the left of the growth the vessel wall appeared to assume its normal structure and proportions. The dilatation which practically involved the whole of the arch was uniform, and the mass was spherical rather than spindle-shaped. Detailed autopsy findings are given, together with a photograph showing the site of rupture in the thickened fibrinous wall of the sac in which was partially imbedded the clump of silver wire.

The Fat Content of the Tonsils and Its Relation to the Processes of Metabolism and Infection.—J. Wright gives a résumé of the literature of fat in lymphoid tissue, and notes that his recent researches have led him to conjecture that some of the spaces frequently noted in such tissue are due to fatty degeneration and that this is one of the processes of tonsillar regression. It has been noted in the removal of faucial tonsils, involving forcible pressure that an oily fluid has exuded from the tissues which was not merely the result of an agglutinated lacuna. Examination was made of a tonsil on which there had been a white area supposed to be a gumma. This area was incised, and an oily fluid exuded. Sections of the tonsil stained with osmic acid showed a cavity formed by the metamorphosis of the lymphoid cells into fat or their granular degenerations and replacement by fatty matter. Examination of a series of unselected tonsils invariably revealed fat droplets in the cells, as well as in the intracellular spaces, both of the stroma and of the lymphoid tissue. Fat in the form of droplets may migrate into degenerating as well as into normal tonsils. It is natural therefore to conclude that some of the intracellular fat is normally derived from the passing food, but it cannot be said that it all comes from this source. As a control in a series of cases the tonsillar surfaces were smeared with butter a few minutes before tonsillotomy. In these cases the distribution of the fat was relatively exactly the same as in the other cases, but the increase in quantity was everywhere very marked.

Journal of the American Medical Association, December 22, 1906.

Renal Tuberculosis.—L. Freeman remarks that the old notion that renal tuberculosis was secondary to that of the bladder is now exploded and its hematogenous origin is very generally recognized. This view, supported by clinical experience, is also supported by the experimental findings of Baumgarten that tuberculous infection in the genitourinary system follows the flow of the secretions, from the testicles to the prostate and from the kidneys to the bladder. Renal tuberculosis is generally at first unilateral, and in spite of the fact that it may occasionally become latent for longer or shorter periods, its usual course is progressive, and experience has demonstrated that early nephrectomy, before involvement of the bladder occurs, is the best treatment for unilateral renal tuberculosis, provided the general condition of the patient permits. The existence of tuberculosis elsewhere, if not too far advanced, is not a contraindication; even bad cases of vesical tuberculosis may improve or recover after operation, as has frequently occurred in Freeman's experience. It should be remembered, too, that the tuberculous disease of the bladder is often only apparent, as a reflex from the kidney or the result of irritating discharges. The one essential to be kept in view is that the other kidney must be sound, both as to function and tuberculosis, and an occasional exploratory lumbar incision may be required, though, as a rule, this is ascertainable by other well-known methods. The weight of authority is against partial nephrectomy, and nephrotomy is never indicated except to relieve suffering in case nephrectomy is impossible. It cannot cure, and almost always leaves a troublesome urinary sinus. The removal of the ureter is not ordinarily indicated. If sinuses result they usually heal after nephrectomy.

Nose and Ear Suppuration and Facial Erysipelas.—C. F. Welty accounts for the special frequency of erysipelas in the face by its nearness to the source of infection in the nose or ear. The pus secretion produces an abrasion of the skin or mucosa and inoculation follows. This may also be conveyed by the handkerchief, or, more frequently, he thinks, by the finger. The reason for the so frequent recurrence of facial erysipelas is, he says, because the infection is always present and is practically never eliminated without operation. When streptococci can be determined in the secretion of the ear or nose it should be considered as an established fact that the erysipelas is dependent on them. The reason why 82 per cent. of facial erysipelas starts from the angle of the nose is thus explained. The reason that erysipelas does not occur in every case in which

streptococci exist in the secretions is best given by assuming immunity of modified virulence; not every case of exposure to other infections is followed by the outbreak of the disease. These opinions are supported by the results of the examination of some sixty cases of erysipelas in the city and county hospitals at San Francisco. Idiopathic facial erysipelas, Welty says, is a misnomer.

Retroperitoneal Cysts.—F. D. Donoghue summarizes some of the leading diagnostic points of Wolffian body cysts in substance as follows: A cyst derived from the remains of the Wolffian body develops back of the retroperitoneum and may push the stomach in any direction, or may develop behind and displace forward the aorta and vena cava. True pancreatic cysts would not be likely to do this on account of the relations of the parts. The greater the amount of substance secreted and the amount and number of products from the displaced ectodermal and mesodermal cells, the larger the cyst. Lateral mobility, which has been considered diagnostic of mesenteric cysts, is also characteristic of most tumors of the upper abdomen which do not develop from a glandular organ. A starch-converting ferment is not always present in undoubted pancreatic cysts and has been found in abdominal cysts not connected with the pancreas. Slowly developing obstruction to the pancreatic duct or from interstitial changes, may cause cystic degeneration of the pancreas. Pancreatic cysts are firmly fixed and reach a larger size. Three forms of so-called pancreatic cysts have been described; one, the true, small, firmly-fixed pancreatic cyst; another, the thin-walled, friable pseudocyst, full of pigmented material presenting below the stomach with areas of dullness above and below, and third, a thin, fibrous-walled cyst of large size, containing, as a rule, cholesterin fluid, freely movable, and can be enucleated; it resembles closely a parovarian cyst and develops in close relationship to the pancreas. These are the true Wolffian body cysts, standing in the same relation to the pancreas as do paraovarian cysts to the ovary, and he suggests for them the name "parapancreatic cysts." Aspiration should never be attempted on account of the danger of infection, either by puncture of some hollow viscus or by dissemination of cyst contents. His conclusions are given as follows: "The clinical picture of a cyst developing behind the peritoneum from embryologic remains, depends on the relations it finally assumes. Cysts from the Wolffian body are not uncommon in women. Movable cysts presenting in the epigastrium have usually been called pancreatic, although true cysts of the pancreas are rare (especially in women) and are rarely movable. Developing in the region of the kidney, they may be mistaken for hydronephrosis or may extend so low as to be considered ovarian. Retroperitoneal cysts are usually benign, unaccompanied by symptoms other than those of a mechanical nature.

Tetanus Neonatorum.—J. M. Anders and A. C. Morgan call attention to the wide distribution of infantile tetanus, its special frequency among negroes noticed by southern physicians, and the terrible infectiousness of the disorder in local epidemics. They say that in the light of our accurate scientific knowledge of this disease, the necessity of absolute asepsis in confinement cases, and especially in the care of the cord, should be insisted on. To this end the registration of midwives should be required by law. The medical colleges should give more attention to the subject and instructions as to the simple methods of prevention should be sent out by boards of health, charity societies, etc.

Hymenolepis Nana and Hymenolepis Diminuta.—Four additional cases of the occurrence of *Hymenolepis nana* to those already reported from the United States are published by W. H. Deaderick, who describes the parasite and the method of its detection. It may require, he says, repeated doses of male fern, the only remedy of value, thoroughly to expel the worms, and they are often difficult of detection in the feces after expulsion. They resemble minute opalescent shreds of mucus and the greatest care is needed to avoid overlooking them. He examined for them in a large flat baking pan, painted black, with perforations in one end so that the liquid feces could be retained or poured off without agitation. These cases were discovered during an investigation he was making as to the frequency of uncinariasis, and the finding of so many cases in a limited study leads him to think that the parasite may be of more common occurrence than has been generally supposed. He also reports a case of *Hymenolepis diminuta* in a child, the twelfth on record, discovered like the others while searching for the ova of uncinaria.

French and Italian Journals.

Lavage of the Ureter in Blennorrhagia.—Duchastelet in an address before the Association Française d'Urologie said the ureter, like the bladder, was more sensitive to distention than to contact. The lavage of the anterior ureter without use of the catheter was often painful, the sensitiveness being greater when the mucous membrane showed hyperemia from acute ureteritis and had ceased to be flexible. A rubber catheter, not larger than No. 12, could be introduced; by means of this the injection could be made at once, so that the liquid preceded the catheter into the ureter. Thus surrounded by the liquid, the catheter would hardly come in contact with the mucous membrane and the irritation excited by contact would be almost nothing. The use of cocaine should be exceptional. It prevented the gauging of the sensitiveness of an inflamed mucous membranes to distention while it did not prevent the resulting congestion and might be a source of infection. By the use of a liquid flowing freely back along the catheter, such as a very weak permanganate solution, ordinary treatment could be resumed in a few days.—*Le Bulletin Médical*, October 20, 1906.

Chronic and Multiple Abscesses Due to a Fungus.—Lesné and Monier-Vinard report that they have had under their care a patient with an unhealed abdominal abscess. When the patient entered the hospital the abscess was a crater-shaped cavity the size of a marble; the surrounding skin was purple and infiltrated, the edges sinuous, the bottom sanious and grayish. Two small nodules developed two days after the patient entered the hospital. One was on the anterior external surface of the right forearm, the other was in the right deltoid region. The one on the forearm, after lancing, soon resembled the abdominal abscess. After the one at the level of the shoulder was lanced, two stitches were taken and healing took place quickly. Cultures of the thick, yellowish, homogeneous pus in various media showed characteristics of the mushroom family. With morphological differences according to the media employed, an abundant mycelium was apparent. It consisted of entangled filaments and of rounded masses which were detached, sometimes from the body, sometimes from the filaments. These rounded masses appeared to resemble yeast.—*Bulletin et Mémoires de la Société Anatomique de Paris*, May, 1906.

Cervicofacial Actinomycosis.—Dubreuilh reports the case of a patient, with tumefaction of the right cheek accompanied by trismus and pain in an upper right molar. The tumefaction has continued six years, several abscesses having appeared. The patient is well developed bodily, but not mentally. On the right cheek is a large, hardened subcutaneous surface, not sharply defined, adhering to the deeper parts. This hardened surface includes the temple and the region of the masseter about the external auditory canal and extends also from the forehead to the edge of the inferior maxilla. Adhering to this surface are four small fluctuating projections showing a fungous growth. These protuberances when pressed discharge a clotted pus mixed with blood; the pus contains a large number of yellow grains varying in size from one-fourth of a millimeter to one-half of a millimeter. The patient has not been in the habit of chewing straw or oats, but has often slept on straw. The teeth are good, but the jaws are swollen. Treatment most of the time has consisted of iodide of potassium. A tumefaction still exists from which a drop of pus has been obtained containing round, whitish grains that show under the miscroscope the usual structure of actinomyces. The lesions, although not cured, are now somewhat better.—*Journal de Médecine de Bordeaux*, October 21, 1906.

Abscess of the Liver.—E. Micheleau in an article on hepatic suppurations, classifies sanguinous suppurations into those of arterial origin coming from the general circulation through the hepatic artery, and those of venous origin coming from the intestinal circulation by means of the portal vein. The lymphatics have little part in the disorder. If in a case of dysentery or directly after dysentery along with febrile phenomena pain is felt in the liver accompanied by prominence of the hepatic region, hypertrophy of the liver, fluctuation, a slight tinging of the conjunctiva, digestive trouble, slight edema of the lower limbs, and some other symptoms, arterial abscess of the liver may be diagnosed, although this does not always follow. The abscess rarely heals if left to itself. Only in exceptional cases is it encysted, and the pus reabsorbed. It is also rarely healed by spontaneous opening and discharge. The treatment must be surgical. Puncture of the liver with aspiration is dangerous and is now seldom employed. Laparotomy with incision of the liver is the comparatively simple operation for an abscess of the inferior surface. An operation for an abscess of the superior surface is delicate and complicated. Preventive treatment, which is advocated by certain authorities, consists mainly in the use of enemas from the first stage of the dysentery: large enemas of permanganate of potassium and nitrate of silver, and intestinal and hepatic antisepsis through doses of salol.—*Gazette des Hôpitaux, Civils et Militaires*, October 13, 1906.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held December 6, 1906.

THE PRESIDENT, DR. CHAS. L. DANA, IN THE CHAIR.

Xanthin as a Cause of Fever and Its Neutralization by Antipyretics.—Dr. A. R. MANDEL read this paper. He said that the etiological factors which had been advanced as to the cause of fevers had been mostly studied along lines having the products of metabolism as a basis. They knew that the metabolism in the body was markedly increased in fever and various products had been especially studied by various observers. If they had increased metabolism in fevers, they must expect an increased destruction of cells and tissues, and as among the chief products of cells were nucleoproteids, an increased cleavage of this body would lead to an increased production of purin bases. They knew that among the products of the cleaveage of nucleoproteids they had bases, purin bases, and pyramidin bases. In 1904, at the request of Dr. B. Farquhar Curtis, he examined the products of metabolism in aseptic fever and found a striking resemblance between the increase of purin bases eliminated in the urine and the course of the fever. In all the cases examined patients were given a purin free diet, consisting principally of milk, to prevent the introduction of any exogenous purin. They had found that the normal elimination of purin bases on a purin free diet varied from twenty to thirty milligrams. In one of the typical cases examined, a case of hernia, primary union, no infection, the purin bases rose and fell with the average twenty-four-hour temperature, and in this case he obtained as high as sixty milligrams of purin bodies. In a case of pneumonia the purin elimination was as high as sixty-seven milligrams and followed the temperature. In a case of typhoid fever they found purin elimination as high as sixty-four milligrams. The coincidence between the temperature and purin bases led him to make experiments to prove that purin bases, when introduced in the blood, would influence temperature. He concluded his paper as follows: (1) These observations indicated that in fever there was a distinct relationship between the rise in temperature and the appearance of certain incomplete products of cell oxidation as shown by the excretion of purin bases. (2) The supposition that these bodies were among the substances directly concerned in the production of fevers was strengthened by the fact that the administration of xanthin and caffeine in large amounts would produce a rise in temperature in otherwise healthy individuals. (3) That salicylic acid might neutralize temperature produced by xanthin, either by forming some chemical combination (not as yet established) or neutralize its action on the heat-regulating apparatus.

Dr. GRAHAM LUSK said that the waste of tissue and toxic influences in typhoid fever might be the equivalent of ten grams per day, and amounted to about three hundred grams of flesh day after day, and day after day. The body lost proteid tissue through toxic influences which could not be prevented by giving food of any sort. In pneumonia this toxic waste might be the equivalent of five hundred grams of meat per day; and when this was destroyed the purin bases passed into the blood. It was perfectly possible to eat five hundred grams of meat without rise of temperature. The purin bases of five hundred grams of meat under normal circumstances and in a normal person would be absorbed and pass through the liver, not being oxidized in the liver, but pass to the tissues and oxidized there to uric acid; then one-half the uric acid so formed in the tissues passed to the kidneys and so eliminated, while the other one-half passed to the organs for destruction. If there were no toxic influences one could imagine that when the purin bases occurred in metabolism, instead of being oxidized as normally, passed into the blood stream and passed in larger quantities to the heat-regulating centers, affected them, and so produced vasoconstriction and the other factors which accompanied heat rise.

The Effects of Water on Gastric Secretion as Shown in Dogs with Pawlow Fistula.—Dr. N. B. FOSTER read this paper. He said that if a large amount of fluid was taken with the meal, more acid secretion or a more prolonged digestion would be required. From the point of view of the physician, should drinking at meals be advised? No, because too much water demanded more gastric juice or a prolonged digestion. What he gave was a scientific basis for teaching the medical profession at the present time regarding the effects of the intake of water on gastric digestion under normal conditions, but not under pathological conditions; as yet they had no data on which to decide the latter.

Dr. A. V. S. LAMBERT explained what a Pawlow's stomach was. It consisted of a portion of the stomach segregated by a specially devised procedure, so that a normal connection was maintained between this segregated part and the pneumogastric nerve. A pouch was made from the greater curvature, leaving the lesser curvature and the pylorus intact, the nerves coming to the cardiac end remaining uninjured.

Dr. A. N. RICHARDS said that the most striking fact brought out was that if a certain amount of food was taken with a large amount of water, more juice and more acid were required to carry digestion on. Pawlow introduced two causative factors in the secretion of gastric juice: (1) the psychical, resulting from appetite, and (2) the reflex; cutting the pneumogastric prevented the secretion of gastric juice. The second factor was what he termed chemical excitation, and cutting the pneumogastric had no effect on the secretion of the gastric juice. Pawlow's idea was with regard to the second causative factor, that certain substances in contact with the mucous membrane of the stomach set up reflexly the secretion of gastric juice, and he advanced the same idea with regard to the pancreatic juice. In the latter the acid chyme passing through the duodenum called forth nervous reflexes setting up pancreatic secretion. Acid in the duodenum resulted in the introduction into the blood of certain substances which came in contact with the pancreatic cells, exciting the gland to activity. It had recently been shown that the same state of affairs existed in the stomach, *i.e.* from the mucous membrane in the stomach certain substances got into the circulation and called forth the secretion of typical gastric juice. The fundus yielded none of this gastric secretion. If a small amount of fluid food was introduced it would naturally remain in contact with that portion of the stomach, and would not be able to call forth secretion; but if one increased the bulk, one would expect more gastric secretion to be formed. To him this seemed a more rational explanation of the chemical secretion due to chemical stimulation of the gastric glands.

Experimental and Practical Work on Rabies.—Dr. D. W. POOR presented this communication, which was read by Dr. Ira Van Giesen. He said that the Pasteur method of treating rabies was established at the Research Laboratory in 1899 and the following figures gave an idea of the extent of the work done: In 1901 there were 29 cases treated; in 1902, 44 cases; in 1903, 71 cases; in 1904, 89 cases; in 1905, 122 cases; and so far in 1906, 291 cases had been treated or were still under treatment. Since January, 1904, the treatment had been mailed to 295 cases, of which 18 were severe, and 277 moderate or mild. Out of this number there had been but one death, a mortality of .3 of 1 per cent. During the same time 151 cases were treated at the laboratory, of which 22 were severe and 131 moderate or mild. In this number there was also one death, giving a mortality of .6 of 1 per cent. Dr. Follen Cabot had undertaken experiments to determine the effect of different caustics on rabic virus twenty-four hours after its entrance into a wound. These experiments in-

volved the use of 287 guinea pigs as test animals. The results of these experiments showed that with nitric acid 91 per cent. of the animals were saved, with the actual cautery, 67.6 per cent., with silver nitrate, 50.9 per cent., and by simple swabbing out of the wound, 31 per cent. Another question being investigated now was how to shorten the time required for the production of immunity in rabies. It was well known that the Pasteur treatment failed to protect occasionally when the patient had been severely bitten upon the head, because the virus reached the brain before the expiration of the time required by the treatment to immunize the patient, which was about four weeks. They had records of eight patients who developed rabies within this four weeks. If such cases were to be protected it was necessary first to destroy as much of the virus as possible, and to hasten the immunization of the patient, or prolong the period of incubation of the disease. This latter object might be accomplished by increasing the amount of antirabic immune body in the patient's blood as rapidly as possible without decreasing the resistance. He then cited a few results which indicated that it was possible to prolong the incubation period in guinea pigs by injecting them with immune serum. Another problem related to the making of a rapid diagnosis in animals supposed to be rabid. The microscopical method of diagnosis based on the pathological findings of Negri in 1903 had been greatly improved upon by methods introduced by Drs. Williams and Van Giesen, whereby smears from the brain and stained by a special method permitted of a diagnosis being made now in a few minutes. Dr. Williams had pursued the study of the pathology most extensively, and by investigations in comparative morphology and along other lines had accumulated a large amount of evidence to show that the so-called Negri bodies were protozoa and the causative agent of rabies. He believed that it was worth while for a municipality to provide for the thorough investigation of this disease, and for the treatment of those of its citizens who might be exposed to it, as was being done extensively of late in various cities; but he believed that in addition more attention should be paid to the other side of the question, the enforcement of legislation that would prevent the running at large of ownerless dogs, which kept the disease always with us.

Dr. W. H. Park said that many physicians did not know what to do when a person was bitten with a rabid dog. To-day physicians could have a very quick diagnosis made, whereas when they first started the Pasteur treatment and injected rabbits, it took weeks before they knew whether or not an animal was rabid. Dr. Williams, in trying to find the etiology of rabies, saw and described the Negri bodies even before Negri's article reached them. A safe diagnosis could now be made within twenty minutes. Dr. Van Gieson had prepared a stain which enabled them to do this much more easily. Even in animals decomposed almost beyond recognition they were able to find the bodies. Physicians would not remember the great need of proper cauterization of the wounds in these cases; the actual cautery or nitric acid which penetrated deeply should be used. The Pasteur treatment could now be mailed all over the country. The treatment was free to those residing in New York.

Eosin-Immunity in Tetanus.—Dr. Simon Flexner addressed the members of the academy on this subject. He said that one year ago he had studied the effect of injections of eosin into rats inoculated with the tetanus bacillus; he found that using a solution of eosin, of not too high a degree of concentration, injected successively on several days a very considerable percentage of the animals thus treated would be saved from death due to the tetanic infection. In some of these animals symptoms of tetanus developed; in others no symptoms whatever developed. All the animals inoculated in this way developed tetanus when not treated by eosin. Eosin in certain concentrations had the power to suppress the development of the spores of the tetanus bacillus. Eosin tended to detoxicate the organism and rendered the organisms inert as poisons. It prevented the development of spores, or else retarded or diminished this development. If these animals could be kept for a period of many months and then an attempt be made to reinfect them, interesting facts would be presented. Dr. Flexner showed an animal that had been inoculated three months ago with tetanus spores. The animal had been treated by injections of eosin, had developed no symptoms of tetanus, and recovered. Four days ago the animal was injected with the tetanus toxin which represented a distinct tetanic dose, and yet was less than a lethal dose. This dose was repeated. Two days after the second injection occurred the first appearance of tetanic symptoms, but on the side of the animal where the spores were not injected. This was an instance of a local immunity.

Dr. F. C. Wood said there were many theoretical questions that had not been answered. One was the method of action by which fluorescent substances produced lesions. Since the introduction of the *x*-ray and radium rays in the treatment of malignant growths this action was seen; the same necrosis was noted in animals injected with fluorescent substances and exposed to light as the necrosis produced by radium. The action of fluorescent bodies suggested the action of eosin on sensitized photographic plates; there was set free some energy due to the production of light. There was a possible liberation of energy by [illegible] there might be set free energy by the organism itself when treated with eosin.

An Experimental Study of the Sensation of Pain in the Abdominal Viscera.—Dr. S. J. Meltzer (with Dr. L. Kast) read this paper. (See page 1017.)

Dr. Joseph Collins said that the experiments of Dr. Meltzer went a long way toward solving the intangibility which surrounded visceral or abdominal pain, and, although apparently solving it, he really made the solution more difficult, because he left out of consideration the question of the intensity of the pain. If this visceral pain was of considerable severity it would be difficult to explain certain observations of dogs eating their own entrails. The experiments of Dr. Onuf and Dr. Collins showed that when the pylorus of the stomach, the inferior border of the liver, the gall-bladder, etc., were encroached upon there was at once the manifestation of pain in the animal. As bearing on Dr. Meltzer's experiments, one symptom or complex of symptoms now recognized was of great importance. This was the intense paroxysms of abdominal pain associated with splanchnic arteriosclerosis. Here the pain was not unlike that of angina pectoris. In this condition all the viscera being apparently normal acute agonizing pain might occur. This clinical fact would seem to bear directly upon the experiments of Dr. Meltzer and to corroborate the statement that the viscera throughout the abdominal cavity were in reality susceptible to painful stimulation.

Dr. Joseph A. Blake gave his practical personal experiences in regard to the sensitiveness of the peritoneum covering the abdominal viscera, and said that he had never been an exponent of operations based upon local anesthesia. Although he had not had so much opportunity for observing the sensitiveness of the peritoneum as others, his experience showed that when patients were operated upon under local anesthesia they experienced pain. When one reached the parietal peritoneum and pulled upon it as in hernia it was sensitive. In other operations, as upon the intestines or stomach, the patients suffered pain when the viscera were drawn upon. The pain was not so severe when the viscera were pinched or compressed, but only when drawn upon. It was hard to differentiate the pain from compression, or from tugging, or that caused by pulling. The visceral peritoneum was not so sensitive as the

parietal, or other tissues of the body. In inflamed conditions of the peritoneum the peritoneum was certainly painful. When drainage was introduced into the peritoneal cavity, such as gauze or substances in which the granulations might grow, the withdrawal of this drainage was exceedingly painful.

Dr. Willy Meyer said that his experience with gastrostomy, with enterostomy, with cecostomy, with incisions into the bladder preliminary to a prostatectomy, etc., caused him to corroborate the statements made by Lennander. For instance, pulling forward the stomach in gastrostomy was very painful to the patient, but the incision into the stomach itself did not cause pain. The visceral peritoneum seems not to be painful when handled, but the parietal was very sensitive. The intestines could be squeezed and treated with a very strong electric current without the slightest manifestation of pain. Dr. Meltzer had offered the explanation that cocaine worked upon the general nervous system, probably upon the brain, thus explaining why surgeons did not note the manifestation of pain in the patient when handling or cutting the intraabdominal viscera in cases operated on with the help of local cocaine anesthesia. He asked if he thought it was plausible that the very small amount of cocaine so often injected and used for local anesthesia would be sufficient to produce such an effect on the general nervous system. Dr. Meyer hardly thought so. He also called attention to the amount of cocaine used. If it were permissible to compare the weight of animals with that of men regarding the doses of the drug, it appeared that ten to fifteen times more cocaine was used in these experiments than corresponded to the medicinal doses allowable in our daily practice. Dr. Meyer considered it of great importance that Drs. Meltzer and Kast had approached this question in an experimental way, and he had no doubt that they would come to definite conclusions. At present he believed that further investigations were necessary to determine conclusively the correctness of Dr. Meltzer's findings.

Dr. Meltzer closed the discussion.

Election of Officers.—*President,* Dr. John A. Wyeth; *Vice-President,* Dr. Algernon T. Bristow; *Trustee,* Dr. Charles A. Dana; *Member Committee on Admissions,* Dr. J. Ramsey Hunt; *Member Committee on Library,* Dr. Henry S. Oppenheimer; *Recording Secretary,* Dr. John H. Huddleston; *Corresponding Secretary,* Dr. Charles Stedman Bull.

SECTION ON SURGERY.

Stated Meeting, Held December 7, 1906.

Dr. Samuel Lloyd in the Chair.

Two Cases of Cured Trigeminal Neuralgia.—Dr. A. V. Moschcowitz presented these patients.

Case I was in a man who had been under observation for three and a half years. When he first came to him in the spring of 1903 he had neuralgia involving mainly the inferior dental nerve. He resected one inch of this nerve, and the patient went home apparently cured. He was relieved of his symptoms for some months, when there was a recurrence of symptoms and he returned to the hospital. It was suggested that the best thing to do was to extirpate the Gasserian ganglion, but he again did a peripheral operation, resecting one and a half inch of the nerve. As he was not cured by the first operation, the proper thing to do was to attempt to prevent the renewal of the divided nerve. He, therefore, took silver leaf and packed the canal in the lower jaw. He was cured for eight months and again the old symptoms returned. The patient again returned to the hospital and he found a small quantity of silver foil still in place and a large quantity of cicatricial tissue. Again the canal was packed tightly with the silver. It was too soon to say whether the patient would remain cured although there had been complete relief of symptoms since the last operation. An *x*-ray picture showed the silver foil packing. There had resulted no facial paralysis at all.

Case II was that of a woman who was sent to him last June for resection of the Gasserian ganglion. When he examined the patient he found not only a trigeminal neuralgia including the three branches of the nerve, but a polypus as well. This was removed, but the patient was as bad as ever, and was then admitted to Mt. Sinai Hospital, and the operation performed last July. The nerve was divided at its exit from the foramen and in it he hammered a specially devised nail of rivet form, so entirely closing the foramen. She had remained free from pain ever since. The *x*-ray plate was shown.

Dr. William M. Leszynsky said that he had had the second patient of Dr. Moschcowitz under his care at the hospital and she had apparently made a perfect recovery under medical treatment, and had been free of symptoms for one year. While there was no spasm of the face, it was a typical case of trigeminal neuralgia involving all the branches. The treatment consisted of rest in bed, proper dieting, castor oil and strychnia injections. After two or three weeks she was up and around the ward and without symptoms, and was then discharged. Dr. Leszynsky said he had always held surgical interference as a *dernier resort.*

Dr. A. A. Berg asked if the cases presented were severe in character.

Dr. Moschcowitz replied that both belonged to the severe type of the disease. Attacks lasting two or three minutes were induced by touching the parts or efforts at mastication.

Schlösser's Treatment of Trigeminal Neuralgia.—Dr. Otto G. T. Kiliani read this paper. (See page 1019.)

Dr. George W. Jacoby said that any one who had any experience with trigeminal neuralgia recognized the futility of the various measures and methods advised during the last few years. These various methods advised he divided into surgical and medical. Among the former were resection of the nerve, revulsion, obstructive substances as shown by Dr. Moschcowitz, and direct attack upon the ganglion. In the first of these methods recurrences were so frequent that it could only be termed palliative. Some other methods were so dangerous to life that he did not think they were at all times justified in subjecting patients to them. Then there was the injection method, the injecting of various remedies, as nitrate of silver in the vicinity of the nerve, osmic acid, etc. Lately the method had been improved on by injecting directly into the nerve sheath after cutting down upon it. Schlösser's method he believed to be of great worth, although it seemed almost incredible that one could enter the foramina with the needle. The introduction of the needle into the foramen ovale was the easiest, requiring no special technical skill, but great care should be exercised in entering the foramen rotundum; there would be great difficulty here unless the handle of the needle was pressed well forward. He also referred to the dangers of injecting into the ophthalmic division of the fifth nerve in the sphenoidal fissure, where ran the third, fourth, and sixth nerve and the ophthalmic vein. By one injection one might inject in the foramen ovale and then into the Gasserian ganglion. But one should look out for motor paralysis of the motor root. By these injections one did not get paralysis but spasm. The spasm occurring after the injections (lockjaw) was not of long duration. The operation seemed to require a peculiar adaptability. Every case should be subjected to medical treatment before the surgical, but cases should not be delayed too long. Dr. Jacoby thought that they had in this operation a very thorough and noteworthy measure added to their therapeutic armamentarium.

Dr. A. A. Berg spoke of the great dangers incurred in the operation upon the Gasserian ganglion, although recent figures showed there was a comparatively low mortality.

Dr. Hartley's assistant's last twelve cases recovered. As a surgical section he did not think they should let pass unchallenged any statement that extirpation of the Gasserian ganglion was attended by such a high mortality as to preclude its application in the treatment of trigeminal neuralgia. All had seen temporary improvement follow the peripheral operation. He had seen severe cases operated upon several times and only temporary relief given. He called attention to the investigations of Dr. Spiller of Philadelphia with Dr. Keen; it was shown that if there was any organic basis behind, causing a fibrosis of the Gasserian ganglion in cases of trigeminal neuralgia, all peripheral operations must eventually not be classed as permanent cures. The Gasserian operation should not be given up; it was worthy of consideration in the desperate cases of neuralgia.

Dr. Moschcowitz said that the mortality of 24 per cent. was not a true one. With regard to the pathology in trigeminal neuralgia he said that he knew there had been examined five Gasserian ganglia in which the extirpation was the first operation that had taken place; these were examined by very competent pathologists and they found these ganglia to be perfectly normal. If a peripheral operation had been done it was possible that an ascending degeneration might have taken place. The majority of observers had found an endarteritis. Therefore, if the Gasserian ganglion was not the cause or the seat of disease, why remove it? In the peripheral operation it was necessary to prevent regeneration of the nerve, and the buttons he showed would do this.

Dr. Wm. Sohier Bryant said that apropos of the etiology of trigeminal neuralgia there were many cases due to intranasal disease, and many cases had been relieved by application of cocaine to the nose. Trigeminal neuralgia might be due to inflammation of the sinuses, by compression, by spurs, by irregular turbinates, or by functional disturbances of the vasomotor system.

Dr. Wm. M. Leszynsky thought the method of treatment advised by the reader of the paper which would relieve patients for ten months should be heeded; when recurrences occurred again the patient might be relieved for another ten months; this could be kept up all the patient's life and without any danger attached to it. He congratulated Dr. Kiliani upon the presentation of this method.

Dr. Robert T. Morris said that many patients came to him that had not had careful examination of the nose or eyes; many of these cases he had found did not require operation at all on the nerve. Within the past year he had had two cases of trigeminal neuralgia which were cured by proper attention to an accompanying eyestrain.

Dr. Kiliani said that the introduction of alcohol into the nerve sheath was not a peripheral operation. It was a fact that when alcohol was injected it hardened the tissues; after the anesthesia passed off, strange to say, the sensibility recurred but not the pain. Why this was so he could not answer. It was a fact that for ten or twelve months the pain disappeared.

The X-Rays Versus Surgery in Sarcoma.—Dr. Aspinwall [illegible] read this paper. (See page 1020.)

The Choice of Procedure in Cases of Loose Kidney.—Dr. Robert T. Morris read this paper. He said that too much, as well as too little, operating had been done for loose kidney, and asked what should be our choice of procedure in advising patients, and how should they proceed to operate in cases selected for operation. The following classification seemed to him to be a useful one: (1) Loose kidney present, but causing no disturbances. (2) Patients with major or minor psychoses associated with, but not influenced by, the presence of loose kidney. (3) Patients with minor or major psychoses precipitated or intensified by the presence of loose kidneys. (4) Patients with various gastrointestinal reflex disturbances, depending upon the influence of loose kidney through the large sympathetic ganglia. These were the cases that gave the most brilliant results. (5) Patients with direct local mechanical results from the influence of loose kidney. (6) Patients in whom loose kidney was only a part associated with other visceral ptoses. What treatment should be proposed for loose kidney cases? Abdominal supporters first of all in the panptosis cases. Abdominal supporters should be applied in cases where there was any doubt about the part played by a loose kidney. Some of these patients would get so much relief that they would not ask for operation; others were benefited just enough to prove that one must operate. Dr. Morris said he had tried all the type methods excepting the new one proposed by Longyear of shortening the nephrocolic ligament, and this seemed to be disposed of in the combination operation which was now employed. The combination operation included the suture of Goelet, which hung the kidney at just the right point, and the iodoform gauze packing of Senn, which disposed of the retroperitoneal pouch when secondary adhesion occurred after removal of the gauze. Patients were out of bed in two weeks after the operation. The only instruments required were a pair of scissors and a needle. The entire operation of fixation of a loose kidney could be done leisurely in fifteen minutes by the combination operation, and he had fixed both kidneys, completing the work in that length of time. Expeditious work was desirable in any sort of surgical work if it left no detail neglected, because it left the patient with natural resistance less impaired than it was after puttering operations. The combination operation was a speedy one, and it left no detail neglected.

Perforation of the Intestine by a Murphy Button.—Dr. Eugene H. Pool reported this case at the suggestion of Dr. Bull. There was a perforation of the intestine by a Murphy button two months after an otherwise successful pylorectomy, the perforation occurring some distance from the site of anastomosis. The patient was a woman, fifty-six years old, who gave a straightforward history of carcinoma of the stomach. Operation was performed on March 30, 1906. At the pyloric end of the stomach a large growth was found which was fairly movable, and a pylorectomy was performed. At the same time a gastroenterostomy was done with a Murphy button of the usual size, but with the flange on, as was suggested by Dr. Weir, and it was in all probability this flange that was the cause of the subsequent trouble. At the end of the fifth week she drove for two hours. On the forty-first day, without any apparent cause, she was seized suddenly with severe pain in the right iliac fossa, accompanied with chill and vomiting. Shortly afterward the temperature rose to 100.5°; pulse, 104. At this time there was local tenderness, rigidity, and general distention. The bowels had moved every day by enemata. The leucocytes were about 9,000 at this time, with polymorphonuclears 87 per cent. These symptoms in the right iliac fossa cleared up gradually, and four days from the onset of these symptoms she felt comparatively well and able to go downstairs. During the next five days there was occasional pain in the right iliac fossa and occasional nausea, and the patient was getting rather weak. At the end of the fiftieth day from time of operation she was seized with a similar attack, *i.e.* sharp pain, vomiting, chill, temperature 101.5°, pulse 124, leucocytes 33,000, and polymorphonuclears 93 per cent. The interesting point here was that the pain was referred to the left iliac fossa and none to the right. The patient became very weak, entered into collapse, and in a few days died. At the time of the first attack the *x*-ray showed the Murphy button to be in the right iliac fossa. At autopsy low down in the iliac fossa was quite a large abscess, four inches in diameter; by careful dissection a narrow tract was found two inches from the ilocecal junction, and an opening was noted through which could be seen the border of the Murphy button. No doubt during the first attack the button had perforated and been walled off, preventing the extravasation of feces and pus.

Dr. CONNER reported a similar case in which the woman gained forty pounds after the operation and had been perfectly well for a long time afterward. The anastomosis between the stomach and intestine by means of the Murphy button gave no trouble for a long time; then it was found that the stomach had twelve ounces of residual food, and the Murphy button was noted in it.

Dr. A. A. BERG said that at the Mt. Sinai Hospital in five years there had been eight cases of fatal perforative peritonitis after the use of the button. One of these occurred on the tenth day after a gastroenterostomy for the relief of bleeding from the stomach. A second case was recorded in which an end-to-end anastomosis was done for a strangulated hernia. The other patients, he believed, had had gastroenterostomies performed on them. Because of this experience Dr. Berg steered clear of the Murphy button.

Dr. A. ERNEST GALLANT said it was a question whether the flange on the button had anything to do with the difficulty in passing through the valve.

Dr. KILIANI warned against the Jaboulay button.

Dr. Pool closed the discussion.

Surgical Electric Burr.—Dr. WM. SOHIER BRYANT presented this instrument and illustrated its action.

Election of Officers.—*Chairman,* Dr. John F. Erdmann; *Secretary,* Dr. Edward W. Peterson.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending December 22, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	320	171
Diphtheria	280	36
Measles	154	6
Scarlet Fever	184	13
Smallpox	6	—
Varicella	110	—
Typhoid Fever	62	10
Whooping Cough	101	11
Cerebrospinal Meningitis	6	10
Malarial Fever	..	..
Totals	1223	257

The Action of Alcohol in Chronic Poisoning with Lead, Mercury, and Antimony.—Cesare Biondi calls our attention to the fact that miners who work in mining ores containing lead, antimony, or mercury are intoxicated by an amount of alcohol which would have no such effect on persons in a normal condition. These persons are in a condition of chronic metallic poisoning and the alcohol has an unusual effect on the organs. These metals produce an alteration in the fine tissues of the nervous elements of the cerebral cortex. Alcohol produces similar alterations in the cerebral cortex in the fetuses of animals into whom alcohol has been injected. Its effect on the already poisoned nerve cells of the miner is much more marked than under ordinary circumstances. The metallic poisoning renders him unable to resist the effects of alcohol, and such persons should not be judged too harshly when they become intoxicated.—*Rivista Critica di Clinica Medica.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 21, 1906.

Cuba, the sanitary aspect of the reoccupation of, 539.
Cumberland Valley Medical Association, 461.
Curies, a scholarship in honor of the, 915.
Cyanosis, microbic, 189.
Cycloplegia, artificial, in errors of refraction, 791.
Cystoscope and ureteral catheter, the diagnostic value of the, 822.

D.

D'Arsonval and other high-frequency currents, 144.
Davis, A. Edward, fitting glasses, etc., 227.
Deafness, electrolysis in the treatment of, 424.
Death, a case of sudden, due to vagus inhibition, 389; penalty abolished in France, 746.
Decidual tissue, diagnostic significance of, 188.
Degrees, a shower of, 421.
Delavan, D. Bryson, the medical museum, 612.
Dentition, the reflexes of, 68.
Dermatitis exfoliativa, 592.
Dermatoses, consanguinity in the etiology of, 382.
Desmoid reaction, the value of Sahli's, 924.
Diabetes and mental troubles, 913; drugs in, 584; oatmeal diet in, 619.
Diaphragm, diagnosis and treatment of injuries to the, 589.
Diaphragmatic eventration, 668.
Diarrhea, appendicostomy and cecostomy for the relief of, 464, 473; in infancy, 155; of infants, an unrecognized etiological factor in the summer, 416.

Dieffenbach, William H., observations on the etiology of cancer, 901.
Diet, as an etiological factor in diseases of the skin, 594; as a therapeutic measure, 594; therapeutic applications of, 383.
Dietetic errors and their effects, 155.
Digestion, disorders of, during the second year, 155; during the first year, 155.
Digestive organs, advances in the physiology of the, 189.
Digitalis and barium chloride, 28; and strophanthus, comparative action of, 762; the use of in valvular heart disease, 1005.
Diphtheria antitoxin, a new preparation of, 475; antitoxin, the dosage of, 475, 680; antitoxin, the prophylactic use of, 546; intravenous injection of antitoxin in, 666; latent, a public health problem, 511; recurrences in, 1008; the complications of, 877; the origin and prophylaxis of chronic, 191; toxin, maternal transmission of immunity to, 577.
Dipsomania, 454.
Disen, Charles F., some points on the diagnosis and treatment of the pretuberculous state, 494.
Disinfection, the fetich of, 347.
Diuretics, mechanism of the action of, 427.
Doctors and newspapers, 421.
Dogs, the immortality of, 186.
Douglas, Charles J., dipsomania, 454.
Dourine, changes in the nervous system in chronic, 347.
Drowned, resuscitation of the, 106.
Drug eruptions, the histopathology of, 505.
Dublin, letters from, 876.
Ductus arteriosus, a case of persistent, 677.
Dullard, education of the, in the public school, 140.
Dunning phthisis camp, the, 303, 384.
Duodenum, the anatomy of the, 348; ulcer of the, from the surgical standpoint, 397.
Dysentery, the relation of ulcerative colitis to, 100; the treatment of chronic, 389
Dyspepsia, is nervous a disease *sui generis*? 425; reflex in abdominal disease, 590.

E.

Ear suppuration, the odor test in, 878; the, as an index of character, 303; the treatment of discharges from the, 76.
Earthworms, the possible importance of, as a factor in the spread of disease, 269.
Eccles, R. G., does the drinking of water give typhoid fever? 201.
Echinococcus cysts, 71.
Eclampsia, 433; pathology, etiology, and treatment of, 173; heredity in infantile, 1008; the etiology of, 913.
Eczema, etiology and treatment of, 667; ocular, in children, 68; oral, 190.
Edema, circumscribed, 675; toxic, 667.
Einhorn, Max, remarks on Banti's disease (splenomegalia and cirrhosis of the liver), 329; Roentgenography of the stomach, 572.
Eiselsberg, operation on Prof., 184.
Eising, Eugene H., obliterative endarteritis of femoral distribution with gangrene of the feet, 739.
Electric currents, effects of alternating of high frequency, 750; light in the treatment of various diseases, 759; sleep, 400.
Electricity in gastric disorders, 757, 758; in joint affections, 757; in ophthalmic practice, 760; in the treatment of disease, 732; in the treatment of disease, 509; the use of high-frequency currents of, 759.
Electrochemical sterilization in cancer of the orbital and nasal regions, 759.
Electrotherapeutics, a plea for conservatism in, 756.
Electrotherapy, the present status of, 757; when is it indicated? 756.
Elephantiasis of the penis and scrotum as the result of syphilis, 593; secondary to chronic cardiac disease, 628.
Emaciation, the treatment of, 346.
Embolism, pulmonary, 111.
Emergency work, surgical diagnosis in, 292.
Emphysema, the hot-air treatment of, 710.
Empyema, antistreptococcus serum in, 347; the sufficiency of simple incision in acute, 348.
Encephalitis, acute nonsuppurative, in children, 197, 519.
Encephalocele, frontonasal, 550.
Endarteritis, obliterative femoral, with gangrene of the feet, 739.
Endocarditis, a case of septic, 517; a case of septic, 761; gonococcus, 763.
Engelmann, Rosa, an urgent plea for the use of larger doses of antitetanic serum for lockjaw, with a case in point, 453.
English, appointment of Dr. David C., 225.
English as she is wrote at International Medical Congresses, 104.
English, D. E., infant feeding, 186.
Enno Sanders prize, the, 421.
Enteritis, intestinal resection for tuberculous, 392.
Enteroptosis, 468; the treatment of, 268.
Enterotomy, the technique of, 520.
Enucleation, in connection with accessory sinus disease, 689.
Enuresis due to urinary hyperacidity, 586.
Epicardium, sarcoma of the, 880.
Epididymitis, antigonococcus serum in, 635; the operative treatment of gonorrheal, 565; the prevention of, 921.
Epilepsy, affection of the spinal cord in, 878; 103 cases of, 490; peculiar attitudes in, during sleep, 625; prize essay on, 871; salt, free treatof, 557; the importance of the early diagnosis and treatment of, 904; the operative treatment of, 506; the opium-bromide treatment of, 1007.
Epileptic fits, cessation of the pulse during, 231; suicide in an, 110.
Epileptics, a second institution for, 830.
Epithelioma, benign, cystic, 625; late results of the *x*-ray treatment of, 907, 930.
Epitheliomata, two on one lip, 930.
Erdmann, John F., obstruction of the common bile duct, 441.
Erie Railroad surgeons, 747.
Erysipelas, and nose and ear suppuration, 1040; maternal causing peritonitis in the child, 997.
Erythema autumnale, 879.
Esophageal stenosis, the treatment of, 150; stricture, the diagnosis of, 263.
Esophagus and upper air passages, direct examination of the, 388; peptic ulcer of the, 426; retrograde currents in the, 190; stricture of the, 846, 885.
Ether and chloride of ethyl sprays in the treatment of anthrax and lupus, 775; more, less chloroform, 859.
Ethmoturbinal cells clinically considered, 550.
Eucalyptus oil in ankylostomiasis, 698.
Ewing, Major Charles B., leprosy as seen in the Philippines, 933.
Exophthalmos, a case of, 674; pulsating treated by ligature of the carotids, 280.
Eye, birdshot injuries to the, 269; inflammations of doubtful origin, 749.
Eyelids, hyperemia in the treatment of diseases of the, 668.
Eyestrain and headache, 892; hints on, 190; incurable, 425.

F.

Facial palsy, treatment of, 36.
Fat necrosis, abdominal, 808.
Fats, injected subcutaneously, the nutritive value of, 499; subcutaneous injection of, 300.
Feces, examination of the, 28; the bacteriological analysis of, 793; the examination of after a test diet, 550.
Feeding problem, phases of the, 515.
Ferguson, honors to Dr. Alexander, 421.
Fertility, the relation of, to social status, 578.
Fever, premenstrual, 456.
Filtration plant for New York, an experimental, 383; plans for a, 460.
First aid cabinets, public, 542.
Fish, Henry Manning, remarks on enucleation; some uncalled for disfiguring operations resulting from failure to recognize accessory sinus disease, 689.
Fissura abdominalis, a case of, 309; and double genitalia, 426.
Fistulæ, locating, 111.
Floors, hot solutions of soda for the disinfection of, 310.
Food adulteration in Germany, 184; impure, 105; preservatives, are they injurious to health? 721; scandals in Great Britain, 261; the quantity of required, 394.
Foot, a method of taking impressions of the weight-bearing surface of the, 752.
Ford, Capt. Joseph H., prize conferred on, 384.
Foreign body in the intestine, a, 953.
Formaldehyde, disinfection of rooms by, 615.
Fourth of July casualties, 65.
Fractures of the thigh and leg, ambulatory treatment of, 75; operative treatment of, 75; the influence of radiography on the treatment of, 1007; the open treatment of, 277; the treatment of, 793.
Fraenkel's birthday, Prof., 784.
Frambœsia tropica in monkeys, 190.
France, the birth rate in, 786.
Franklin, Clarence P., the ophthalmoscope as an aid to the general practitioner, 99.
Freeman, Rowland G., the physical care of school children, 128.
Frenkel, Dr. H. S., lecture by, 872; visit of, 511.
Fresh air treatment of diseases other than tuberculosis, 926.
[illegible] as a food, 617.
Functional disorders, a factor in the causation of and treatment of many so-called, 863.

G.

Gaillard's Southern Medicine, 581.
Gall-bladder and bile passages, 1,500 operation on the, 278; cholecystectomy for cancer of the, 506; diagnosis and treatment of infections of the, 605; operations, the mortality of, 340; surgery of the, 310.

Gallstones, the medical treatment of, 230; intestinal obstruction due to, 500.
Gangosa, 626.
Gardner, James A., chronic urethritis and an improved method of applying medication to the urethra, 980.
Garrulitas vulvæ, 260.
Gastric and duodenal ulcers, the treatment of, 279; digestion, influence of rest, exercise and sleep on, 358; digestion, influence of rest, exercise and sleep on, 750; hyperacidity and gastric symptoms, 308; hypersecretion associated with cirrhosis of the liver, 357; neurasthenia, 431; physiology, experimental work in, 538; secretion, action of coffee and cocoa on, 112; the effects of water on, in experiment dogs, 1044.
Gastrointestinal canal, the permeability for bacteria, of the, 924; clinic, a new, 23; diseases, the classification of, 514; tract, the relation of the, to nervous and mental diseases, 473.
Gastroptosis, observations on, 627; the surgical treatment of, 156; the treatment of, 556.
Gastrostaxis, 838.
Gastrotomy, 576.
Gelatin method of preserving specimens, the, 985.
Genital activity, female, 498.
Gilbert, J. Allen, choice of cows' milk, 644.
Gingivitis, due to autointoxication, 188.
Girl's mind, the danger of overtaxing the, 437.
Glanders, the spread of in England, 1000.
Glandular fever in children, 658; 12 cases of, 18.
Glasses, fitting, and eyestrain, 160, 227.
Gleitsmann, J. W., address of the president at the twenty-eighth meeting of the American Laryngological Association at Niagara Falls, 57.
Glioma of the eyeball, a case of supposed, 928.
Goiter, exophthalmic, the relation of serum treatment to the etiology of, 718; exophthalmic, the serum treatment of, 308; exophthalmic, the *x*-ray treatment of, 389; forced feeding for exophthalmic, 30; forms of exophthalmic, 150; the surgical treatment of exophthalmic, 388.
Golden, William W., a word about Rashid, the leper, 307.
Golley, F. B., two cases of cancer treated by the injection of pancreatic extract, 918.
Goltman, Abraham, trachoma in school children, 622.
Gonococcus infection, the bacteriology of, 763.
Gonorrhea, the cytology of the pus in, 782; the frequency of, and its effects, 996.
Gonorrheal endocarditis, an unusual case of, 236.
Goodhue, E. S., notes on fevers in the tropics, 1020.
Goodman, A. L., quinine fever, 865.
Gould, George M., "fitting glasses," the diagnosis of errors of refraction, the influence of eyestrain, etc., 106; the mysteries and sources of suicide, 361.
Grant, George H., medical education and medical progress, 241.
Graves, William W., the problem of localization in relation to head injuries, 483.
Gray, F. D., treatment of appendicitis, 130.
Grip, the treatment of, 988.
Gulick, Luther H., health of school children, 121.
Gumma, the contagiousness of, 42.
Gynecological operations, 85 abdominal, 794; remote results of conservative, 920.
Gynecology, is it dead? 468.

H.

Hagner, Francis R., the operative treatment of acute gonorrheal epididymitis, 565.
Hair and feathers, researches on the whitening of, 71.
Hall, J. N., pneumothorax with a report of 15 cases, 296.
Hand disinfection, 35; observations on the hot-water-alcohol method of, 754; the value of Ahlfeld's method of, 270.
Hanging, nervous phenomena following attempted suicide by, 111.
Harbin, R. M., suicide, 462.
Hare, Francis H., angina pectoris: its mechanism and treatment, 601.
Hartshorn, Willis E., surgical diagnosis in emergency work, 292.
Harvard Medical School, dedication of the, 303, 460, 500; honorary degrees conferred at the, 542.
Harvey Society lectures, 225, 580, 701, 872, 956; the first, 662; the second, 787; the third, 916; the fourth, 957.
Hastings, T. W., albuminuria; recognition of the albumin bodies in urine, 13.
Havana asylum, a crowded, 661; sanitation in, 785.
Hay fever and bronchial asthma relieved by treatment directed to the antrum of Highmore, 379; palliatives for, 188; the Helmholtz treatment of, 794.
Head and neck, technique of operations on the, 37; extraction of the torn-off, after-coming, 754; injuries, the problem of localization in, 483.
Headaches, constitutional, 792; from aural disease, 792; from pelvic disease, 792; nasal, 1032.
Head's zones in digestive disorders, 317.
Health board, medical opposition to a, 420; inspection, individual, 388.
Heart and great vessels, wounds of the, 280; block, electromotive changes in, 150; block in practice, 429; block, symposium on, 398; bone formations in the, 709; congenital defects of the interauricular septum of the, 38; congenital malformations of the, 994; disease and immunity from phthisis, 39; disease, the management of advanced, 753; disease, the treatment of valvular, 724; massage of the, in apparent death, 513; muscles, multiple rhabdomyomata, of the, 518; rupture of the, 668; spontaneous rupture of the, 229; the study of the spanemic, 387; wounds, suture of perforating, 546.
Heiser, Victor G., quinine in cholera, 185.
Hematemesis, hysterical, 466.
Hematometer, a new, 360.
Hematuria, endemic, 626.
Hemihypertrophy of the face, 1008.
Hemoglobinuria, malarial, 1004; quinine or black water fever, 880.
Hemophilia, the joint affections of, 654.
Hemoptysis, the treatment of, 117.
Hemorrhage, concealed accidental, 353; in the new born, 625; nitrite of amyl in postpartum, 793; occult gastrointestinal, 871; operation in trauma intracranial, 828; salt solution in intraperitoneal, 752; spontaneous intracranial, 37; the diagnosis and treatment of accidental, 500.
Hepatitis, the treatment of ascites secondary to chronic, 393.
Hepatoptosis, or floating liver, 189.
Heredity, a committee to investigate human, 702; and environment as causes of delinquency and crime, 435.
Hernia, suppurating omental, report of a case of, 496; strangulated in an infant, 101.
Herniotomy, femoral, 425.
Hertzler, Arthur E., a possible danger in the therapeutic use of osmic acid, 380.
Higley, Henry A., disinfection of rooms by formaldehyde; comparative bactericidal value of various methods, 615.
Hill, T. C., pruritis ani, 993.
Hip, congenital dislocation of the, 276; results from the bloodless reduction of congenital dislocation of the, 414; the modern treatment of intracapsular fractures of the, 697; treatment of congenital dislocation of the, 36.
Hirschman, Louis J., air dilatation in the treatment of chronic constipation, 218.
Hodgkin's disease, a case of, 886.
Homeopathic committee opposed to single board plan, 460.
Horse serum, sudden death following the injection of, 63.
Hospital car, a new, 384; conference, 659, 745; news, 422, 955, problem, the, 230; reform, 704; reform in a new light, 641; Sunday plan, a new, 831.
Hospitals connected with medical schools, 858.
Hotchkiss, Lucius W., diagnosis and treatment of the acute infections of the gall-bladder, 605.
Humanities and medicine, the, 407.
Humerus, the reduction of dislocations of the, 506.
Hunt, W. L., the modern treatment of intracapsular fractures, 697.
Huntington's chorea and heredity, 838.
Hydrocephalus, surgical treatment of, 38.
Hydrocyanic acid poisoning, 754.
Hydronephrosis, plastic operation for, 745.
Hydrophobia in Germany, 620; Negri bodies in, 110.
Hydrotherapy in the treatment of the insane, 715.
Hymenolepis nana, 1041.
Hyperchlorhydria, gastroptosis in relation to, 949.
Hyperemia treatment, the value of localized, in the treatment of ambulatory cases, 283.
Hypernephroma of the kidney, 472.
Hyperovarie, 579.
Hypophysis of the brain, the morphology of the, 711.
Hypodermic solutions, a test of purity of, 658.
Hysterectomy for placental polyp, 1010.
Hysteria and neurasthenia in women, 157; in children, 73.
Hysterical condition, a new, among school children, 505; mutism, 552.

I.

Ibarra, A. M. Fernandez de, the first physician to tread American soil, 582.
Icterus, the pathogenesis of, 302.
Ilium, fibroma of the, causing obstruction, 707.
Illinois insane asylum, reform necessary in the, 303.
Illinois State Board of Charities, 659, 702.
Illinois State Board of Health, using the, 23; pamphlet issued by the, 105.

Immigration, increase in, 620, 832; statistics, 184.
India's death rate from wild beasts, 501.
Indigestion, acute and chronic, 665.
Inebriates and drug habitués, a plea for the creation of a State hospital for, 508.
Infant life, a plan for saving, 829; mortality from diarrheal diseases, 184.
Infant feeding, 186; simplicity in, 197; the teaching of scientific, 516; why percentage fails, 198; with raw milk, 783.
Infantile mortality and goat's milk, 838.
Infantilism with gastrosuccorrea with tetanus, 680.
Infants, examination of the feces of twenty-five starch fed, 495; overlying of, 581; sepsis in, 517; the dietetic management of, in hot weather, 233.
Infection with *Tænia nana*, with specimens, 628.
Inflammation and peritonitis considered as physiological processes, 741.
Influenza, a new type of, 914; paralysis of the abducens nerve following, 760.
Inhaler, an improved automatic, 679.
Innocent, the protection of the, 963.
Insane, functional derangement of the ears and upper air tract in the, 281; hospital for the criminal, 64; more accommodations needed for the, 830; the care of the in Illinois, 264; the effect of surgical operations on the, 716.

Spine, causes of habitual lateral curvature of the, 921; concussion of the, 585; fracture dislocation of the, 313; the etiology of curvature of the, 576.
Spirochæta duttoni, the passage of, from mother to fetus, 269; *pallida*, demonstration of the, in the preputial nerves, 191; *pallida*, inoculation with the, 506; *pallida*, observations on the living, 271.
Spirochetes, an improved method of demonstrating, 309; in congenital syphilis, 150; in hemoptysis, 1005; in syphilitic infants, 112; in yaws and granuloma pudendi, 753; the question of, 547.
Spivak, C. D., habitual constipation viewed from the standpoint of modern evolution of dietetrics as a physiological phenomenon, 335; the use of oxygen in asphyxia neonatorum, 741.
Spleen, a case of rupture of the, 883; behavior of the, in carcinoma, 547; primary tuberculosis of the, 711; the *x*-ray for enlargement of the, 462.
Splenectomy, a successful case of, 347.
Splenomegaly, the diary of a case of, 887; splenectomy for, in a child, 760.
Spondylitis, tuberculous, in childhood, 73.
Squier, J. Bentley, illustrative cases of prostatic carcinoma, 608.
Stammering and its treatment, 585.
Standardization bubble, the bursting of the, 1027.
Starch, digestion of, by infants, 621; fed infants, examination of the feces of twenty-five, 495.
Stark, Henry S., hospital reform in a new light, 641.
State Board examination questions and answers, Arkansas, Nebraska, Georgia, 889; Georgia, Michigan, 804; Illinois, 974; Michigan, Nebraska, 722.
State institution, need for another, 999; medicine, oration on, 555.
Sterility in the male, surgical treatment of, 636.
Stern, Heinrich, lupulin in the treatment of gastrointestinal diseases, 443.
Stern, Walter G., the results from the bloodless reduction of congenital hip dislocation, 414.
Sternomastoid breathing, 387.
Sternum, fracture of the, 666.
Stevens, John W., the insane lovers, 244.
Stites, Frank M., the importance of the early diagnosis and treatment of epileptic symptoms, 904.
Stokes-Adams disease and cardiac arrythmia, 879; disease, three cases of, 268; syndrome, 429.
Stoll, Henry F., pleurisy with effusion and pulmonary tuberculosis, with cases observed at the Hartford Hospital, 371.
Stomach, a case simulating ulcer of the, 519; acute dilatation of the, 347; and intestine, demonstration of the movements of the, 359; contents, a test for free hydrochloric acid in, 839; contents, sources of error in examinations of the, 222; perforated ulcer of the, recovery, 063; postmortem findings in ulcer of the, 708; postoperative paralysis

and acute dilatation of the, 733; primary sarcoma of the, 236; recent studies in the diagnosis of ulcer of the, 358; Roentgenography of the, 572; surgical intervention in diseases of the, 750; the diagnosis of ulcer of the, 465; the effect of temperature changes on the, 498; the medical treatment of ulcer of the, 504; the prevention of ulcer of the, 921; the relation of ulcer and cancer of the, 625; the surgical treatment of ulcer of the, 546; the treatment of ulcer of the, 1003; thirty-two cases of chronic ulcer of the, 359; treatment of ulcer of the, 204; ulcer of the, 511; ulcer of the, and cancer, 387; ulcer of the, in childhood, 358; ulcer of the, the dietetic treatment of, 952; ulcer of the, the operative treatment of, 924; ulcer of the, some remarks on, 882.
Stone, William S., the puerperal types of sepsis, 213.
Stowell, William L., 103 cases of epilepsy, 400.
Strabismus and epilepsy, 619; the cure of, 540.
Straub, honors for Major Paul F., 580.
Strauss milk stations closed, 542.
Strontium salts, the action of, on the coagulability of the blood, 388.
Stucky, J. A., some mental symptoms due to disease of nasal accessory sinuses, 820.
Student of medicine, a warning to the intending, 381.
Subscriptions, fraudulent taking of, 421.
Sugar determinations, a new method for, 150.
Suggestion, the rôle of, in therapeutics, 946.
Suggestions, two British, 831.
Suicide, 462; attempts at, 231; in Europe, 225; the mysteries and sources of, 361.
Suit against surgeons, 702; by a physician, 785.
Sulphate of hydrogen, toxic action of, 678.
Sulphites, is food containing, injurious to health? 1013.
Sultan of Turkey, the health of the, 831.
Sunday risks, 342.
Suprarenal capsule, anatomy of the, 60.
Surgeons and internists, the mutual obligations of, in the development of gastric surgery, 356.
Surgery, posture as an aid in, 312; self-restraint in, 923.
Surgical principles and theories, 844.
Sutures, capillarity, in intestinal, 38, 269.
Sweating sickness and the rat, 1008.
Symptoms, the treatment of, a rational and scientific procedure, 527.
Syphilis, a case of hereditary, 638; a contribution to the serum treatment of, 754; a family infected with, 29; cerebral, in children, 119; deep injections for, in infancy, 440; does it sometimes spontaneously abort? 637; intramuscular injections for, 68; late hereditary, 600; manifestations of, associated with pulmonary tuberculosis, 93, 117; of the nasal fossæ, 737; the early diagnosis of, 754; the etiology of again, 224; the examination of the blood and tissues in, 1007; the ocular manifestations of hereditary, 997; the pathology of, 503; the routine treatment of, with mercury salicylate, 749; virulent, and its treatment, 838.
Syphilitic parents, a healthy child born to, 634.
Syphiloderm, primary pigmented, 506.
Syphiloma in the internal organs of the new born, 426.
Syringocystoma, 593.
Syringomyelia with immense cavity, 439.
Systolic murmurs, inorganic, in infants, 517.

T.

Tabes dorsalis in a negress, 749; early signs of, 188; experimental in dogs, 1007; syphilis in the pathogenesis of, 191; the history and principles of the methods of motor reeducation in, 966; the treatment of, 757; treatment of, in the preataxic stage, 110; treatment of the gastric crises of, by elongation of the solar plexus, 848.
Tachycardia, the etiology of paroxysmal, 342.
Takaki, K., Japanese naval sanitation, 321; return of Baron, to Japan, 460.
Talmey, B. S., a plea for the simple round-ligament vetrosuspension, 1028.
Tartar emetic in the treatment of tetanus and meningitis, 152.
Taylor, J. C., a plea for early surgical interference in pelvic infections, 772.
Tea and the typhoid bacillus, 784.
Teeth, causes of the loss of the, 69; supernumerary and the Roentgen ray, 390.
Telephone consultations, 106; terrors, 301.
Temperature taking in the groin in children, 545.
Tendon implantation, successful, 633.
Tent colonies, the value of, 580.
Teratology, superstition in, 233.
Testicle, the function of the, 308.
Tetanus, a plea for the use of larger doses of serum for, 453; eosin-immunity in, 1045; Fourth of July, 296; in two brothers, recovery, 879; neonatorum, 198; serum against, 309; the relation of, to the female sexual organs, 389; the treatment of, 278, 618.
Therapeutics based on physiology, 147.
Thomson, John J., acute mastoiditis, its prevention, diagnosis, and treatment, 376.
Throat, examination of the, in chronic infections, 553; oral sepsis in operations on the, 752.
Thrombi, preoperative, as a cause of postoperative complications, 102.
Thrombosis and embolism, postoperative, 469.
Thrush, M. Clayton, a plea for a more thorough course in pharmacy in our medical schools, 492.
Thumb, a plastic operation to replace the, 998; sucking, 67.
Thyroid gland extract, the use of, to shorten the coagulation time of the blood, 278; grafts, 1033; fluid extract of sheep's, in the treatment of cancer, 760; its diseases and treatment, 555; protective value of the, 459; the significance of enlargements of the, 585; migraine, 301; preparations, therapeutic uses of, 800; and parathyroids, a discussion of the, 555.
Thyroidectomy, the operation of, 277.
Tic, an unusual case of, 751; douloureux, peripheral *vs.* intracranial operations for, 513.
Tick fever, spirochetes in, 29.
Ticks and spotted fever, 343.
Tobacco and the auditory function, 466; scrap, 262.
Tongue, cancer of the, 846; fibrosarcoma of the, 885; fibrosarcoma of the, treated with trypsin, 1004; remarkable flexibility of the, 961; tuberculosis of the, 930.
Tonsil, death from suppurating, 148; etiology of hyperkeratosis of the, 554; lymphatic drainage of the pharyngeal, 189; systemic infection through the, 503; the cold wire snare in the removal of the, 791; the diseased, as a factor in respiratory and gastric diseases, 503; the faucial, 878.
Tonsillitis and acute rheumatism, the relation between, 751.
Torek, Franz, the treatment of diffuse suppurative peritonitis following appendicitis, 849.
Toronto, letters from, 67, 345, 423, 623, 833.
Toxin antitoxin union, the, is it chemical or physical? 699.
Trachea, diseases of the, 550; foreign bodies in the, and tracheoscopy, 551; primary tumors and stenoses of the, 551, 883; rupture of the, without external injury, 1004.
Tracheotomy, or incubation stenosis of the respiratory passages secondary to, 668.
Trachoma among immigrants, 343, 460; and its treatment, 18; in school children, 622; investigation, prize for, 581; treatment of, with radium, 667.
Trained nurse, the, in the public schools, 510.
Transposed viscera, 677.
Trauma and diabetes, 302.
Tri-State Medical Association, 264, 872.
Tropics, fevers in the, 1020.
Trunk, deformities of the, in children, 148.
Truth, the search after, 471.
Tubercle bacilli, human and bovine, 1033; the absorption of dead, 505; the dissemination of, by insects, 701.
Tuberculide, 930.
Tuberculin in the treatment of tuberculosis, 169; therapeutic use of, 114.
Tuberculosis, 341; acute intestinal, in adults, 794; among mill workers, 786; among the Indians, 670; among the negroes, 671; and bronchial asthma, 659; antitoxin, 758; a plea for a more rational therapy in, 725; bacteriological findings in cases of, 194; campaign in Berlin, the, 542; campaigns in Chicago, 105; clinic, a, 263; crusade against, in Chicago public schools, 500; diet in, 88, 116; dust as a cause of, 842; duties and obligations relating to, 73; etiological factors in bone, in children, 908; exhibition in Cincinnati, 420; forms of anemia in chronic, 389; hospital for a prison, 343; Hospital, the City's, 745; how can the physician and layman accomplish most in the fight against? 438; human and bovine, 29, 389; hyperplastic, of the intestines and peritoneum, 287; impaired nasal respiration as an antecedent to, 1006; in France, 64; in infants and young children, the arrest of, 673; in pregnancy, 140; in prisons, 877; internal antiseptic treatment of, 425; in the navy, 746; man's natural protective agencies against, 768; metabolism in pulmonary, 390; neuritis in, 69; new hospital for, at Staten Island, 303; nostrums, 670; of the bones and joints, treatment of, 317; of the cervical glands in infants, 516; of the colon, 274; of the glands, action of *x*-rays on, 794; of the intestine in infancy, 516; of the larynx, treatment of, 114, 115; of the larynx, silence in the treatment of, 954; of the mesenteric glands, surgical treatment of, 10; postexanthematous cutaneous, 711; predisposition of the pulmonary apices to, 61; prevention, workingmen's

insurance as an instrument of, 671; pulmonary, and anthracosis, 742; pulmonary, and pleurisy with effusion, 371; question, new aspects of the, 869; results in German sanatoriums, 780; serum diagnosis of, 195; scope of the State sanatorium for, 114; some of the facts that predispose to pulmonary, 447; statistics of diet in sanatoria for, 116; sterile caseous matter in the treatment of, 425; strychnine in pulmonary, 387; studies on immunity in, 195; surgical, 709; temperature variations in pulmonary, 20; the diagnosis of, in infants and children, 118; the dissemination of, 1033; the early diagnosis of, 231, 882; the early symptoms of, 110; the effect of blowing upon wind instruments with reference to, 529; the kidneys in, 194; the limitation of pulmonary, 152; the liver in, 193; the origin of pulmonary, 191; the portals of entry of, 672; the scope and value of the sanatorium in the movement against, 941; the suppression of, 686; the treatment of laryngeal, 268, 879; the treatment of pulmonary, by acids, 506; the treatment of pulmonary, by artificial pneumothorax, 466; the treatment of pulmonary, by hyperemia, 150; the treatment of pulmonary, with electricity, 509; the value of home treatment of, 117; treatment of, with tuberculin, 112, 169; vaccination against, through the digestive tract, 232; what may be accomplished with apparently hopeless cases of, 749.
Tuberculous, baths for the, 385; glands of the neck, surgical treatment of, 318; mothers, nursing by, 63; sputum, the harmlessness of dust from, 547; sputum, the sterilization of, 388.
Tucson, Arizona, the winter climate of, 545.
Tumors, simultaneous, nonrelated in a mouse, 665; treatment of, by ferments, 390.
"Twenty-three cure," the, 517.
Twin, death of the oldest, 831.
Typhoid bacilli, agglutination of, by bile, 270; behavior of the, in the blood, 348; fate of the, in the organism, 38; the cultivation of, on bile, 465.
Typhoid fever, an epidemic of, at Wesleyan, 745, 831; a prolonged case of, 271; diagnosis of, 877; diet in, 429, 596; does the drinking of water give? 201; early feeding in, 753; epidemic, due to infected milk, 421; in Jersey City, 746; epidemic in Scranton, 1035; not an intestinal disease, 396; perforation of the colon in, 793; relapses of, in children, 520; the bath treatment of, 561; the diagnosis of, 30; the infection of, conveyed by an infant, 519; the municipal supervision of, 596; the transmission of, in an asylum for the insane, 389; treatment of, 396; unusual complications of, 348.
Typhus fever, a case of suspected, 500; in Philadelphia, 143.

U.

Ulcers, phagedenic and serpiginous, 596.
Ulnar nerve, as a landmark, 625.
Umbilical hernia, treatment of infantile, 280.
Uncinariasis in Mississippi, 148; the causation of, 878.
Undertaker, examination for, in New Jersey, 226.
Ureter, calculus of the, removed by cystotomy, 231; stone in the, operation for, 637.
Ureteral fistula after gynecological operations, 601.
Ureters, three, demonstrated during life, 521.
Urethra, diverticula and cul-de-sacs of the, 298.
Urethral diverticulum, 665.
Urethritis, chronic, and an improved method of applying medication to the urethra, 980; the treatment of chronic, 514; the use of ointments in the treatment of, 635.
Uric acid, the determination of, in urine, 70.
Urinary nitrogen and clinical significance of the, 232; sediments, permanent preparations of, 30.
Urine, basic and acid equivalents in the, 808; examination, routine, 189; separator, an extravesical, 505; treatment of postoperative retention of, 339.
Uterine appendages, 100 cases of conservative operations on the, 472.
Uterus, abdominal section for trauma of the, 589; anterior fixation of the, complicating pregnancy, 35; changes in fibroids of the, after the menopause, 354; didelphus, pregnancy in, 668; dilatation of the gravid, 32; dilatation of the parturient, 469; etiology of fibroids of the, 583; fibroid tumors of the, 154; fibroids of the, complicating pregnancy, 34; modern surgical treatment of fibroid tumors of the, 135; radical operation in cancer of the, 962; retroversion of the, in relation to pregnancy, 843; shortening of the round ligaments for retroversion of the, 75; symptoms of cancer of the, 962; the Gilliam suspension operation for the, 432; the innervation of the, 1031; the reciprocal relations between the, and its appendages, and the rest of the body, 964; ventrofixation of the, 146; cases of, 354.

V.

Vaccination, compulsory, at Los Angeles, 660.
Vaccines, cases treated by the injection of, 703.
Vagina, preservation of the vault of the, in pelvic operations, 591; the symptoms and treatment of atresia of the, 591.
Vaginal celiotomy, 586.
Varicose veins, two cases of, successfully treated with the *x*-ray, 338.
Vascular tension in chronic illness, 426.
Vas deferens, anastomosis of the, 147; calcification of the, 110.
Vasectomy for disturbances of the male sexual apparatus, 76.
Vasomotors, the importance of, and the best therapeutic results from, 735.
Vegetarianism, East Indian, 395.
Veins, observations on enlarged, in children, 752; results of the transplantation of the, 628; surgery of the large, 950.
Venereal prophylaxis, publicity in, 75; prophylaxis, publicity in, 666.
Ventrosuspension, a plea for the simple round-ligament, 1028.
Vermont State Medical Society, 703.
Vermont State Tuberculosis Commission, 660.
Vesical fistula, the repair of, 472.
Vienna, letters from, 27, 266, 345, 835, 876, 1038.
Virginia State Medical Society, 501.
Vomiting, the etiology of recurrent, 520.

W.

Waite, Lucy, shock, 367.
Walker, Emma E., the effects of absinthe, 568.
Wallace, Charlton, some etiological factors in bone tuberculosis in children, 908.
Walsh, James Lawson, an unrecognized etiological factor in the summer diarrheas of infants, 416.
Warren, retirement of Dr. John C., 703.
Washington State Medical Association, 499.
Water analysis, a perfect method of, 999; and milk supplies, control of, 158.
Watters, W. H., the gelatin method of preserving specimens, 985.
Weight and length in infancy, 515.
Wertheim, visit of Professor, 620.
Western Surgical and Gynecological Association, 461.
West Virginia State Medical Association, 23, 65.
Wet nursing, modified, 515; of foundlings a pernicious practice, 233.
Whistle nuisance, a mitigation of the, 869.
White spot disease, 594.
Whooping cough and its treatment by an improved abdominal belt, 886; chloroform in, 420; the microbe of, 343; treatment of, by chloroform narcosis, 70.
Wiener, Joseph, prostatectomy in diabetes, 944.
Wilkes, W. O., report of a case of cerebrospinal fever, 778.
Williams, Charles M., late results of the *x*-ray treatment of cutaneous epithelioma, 907; the contagiousness of gumma, 42.
Winston, John W., pathology, etiology, and treatment of puerperal eclampsia, with a plea for the kidneys, 173.
Wisconsin State Medical Society, 65.
Wood, William C., hospital reform, 704.
Working Women's Protective Union, 956.
Wounds, dry tetanus antitoxin as a dressing for, 613; the closure of aseptic, 33; the making and dressing of, 750; the treatment of fresh, with dried-out dressings, 754.
Wyeth, John A., surgical operations in two stages, 919.

X.

X-rays, value of the, in ocular therapeutics, 545. (*See also Roentgen rays.*)
Xanthin as a cause of fever, 1044.

Y.

Yale Medical School, gift to the, 831; requirements, 954.
Yale, the late Dr. Leroy M., 956.
Yellow fever, a case of, 38; at New Orleans, 64; in Cuba, 580, 619, 660, 871, 955; in Louisiana, 303; in Mexico, 264; inoculated in monkeys, 871; on a transport, 746; prophylaxis in Central America, 460.
Young, how may the medical and teaching professions cooperate to improve the moral, mental, and physical condition of the? 402, 436.

Z.

Ziegel, H. F. L., a case of perforation of the soft palate, due to tertiary syphilis; staphylorrhapy, 867.
